Equations (18) give a simple model of the spatial spread of rabies by fox, where D is the diffusion coefficient of the infectious foxes and β represents the rate of infection per susceptible per unit density of infectives. More sophisticated versions of such models that are used today to model epidemics (both in humans and in animals) can capture other effects such as secondary outbreaks.

The above discussion has mainly concentrated on the applications of the traveling-wave solutions of the RD systems. However, a much richer solution structure exists in these systems. In fact, the spectrum of possibilities ranges from simple stationary (or time independent) solutions up to complicated spatiotemporal chaotic solutions.

Perhaps one of the most spectacular applications of RD systems is in morphogenesis. The basic question here is to understand how the complicated process of shaping and patterning in an early embryo takes place starting from a uniform structure, the initial egg. In 1952, Alan Turing proposed that this process could be accounted for in terms of the underlying chemical reactions taking place in the embryo. In his paper Turing proposed some hypothetical reactions that could generate spontaneous symmetry breaking, leading to stable spatial patterns (Turing, 1952). Today this mechanism for spatial pattern formation is called Turing instability (or diffusion-driven instability) in recognition of Turing’s seminal work. A counterintuitive feature of Turing’s prediction is that diffusion can act as a destabilizing force. Murray (1988, 2002) showed that activator-inhibitor RD systems can model the beautiful array of patterns seen on animal skin markings. The idea Murray presented is that at a very early stage, the embryo acquires a “pre-pattern” of chemical morphogens (in Turing’s parlance) that is later read out by melanocytes (pigment producing cells). In this way,

spotted or striped or a combination of both patterns can be accounted for. Furthermore, Murray showed how the geometrical aspects of the RD domain can considerably alter the final outcome of the patterns. This theory explains why spotted animals (such as cheetah, jaguars, and leopards) can have striped tails, but striped animals (such as zebras and genets) cannot have spotted tails. An equally spectacular application of Turing’s theory was proposed by Meinhardt (1998) to account for many patterns seen on seashells.

The book by Murray (2002) contains further references to expanding the above RD framework on modeling crucial processes in morphogenesis, such as feather germs, the initiation of teeth primordia, cartilage and condensation in limb, and epidermis development. Most of them require expansion of the RD framework to incorporate mechanics leading to the study of mechano-chemical models.

With growing evidence of biological morphogens in living tissues, it is now clear that Turing’s theory may play a crucial role in explaining biological development. Furthermore, a recent extension of the applications of RD systems in biological pattern formation has strengthened considerably the theoretical arguments in favor of the role of RD systems in biological modeling. Satnoianu et al. (2001) have shown that coupling of diffusion by advection in the presence of autocatalytic reactions can lead to an improved recipe for pattern formation, which is able to account also for biological growth. The new mechanism of patterning, now termed flow and diffusion distributed structures (or FDS), produces both stationary and traveling structures and, thus, can be viewed as a unifying theoretical construct for many of the patterning processes described above (Satnoianu, 2003). The FDS mechanism is a robust patterning process that can explain somitogenesis in vertebrates (Kaern et al., 2001).

Reaction-diffusion-advection equations have been also used in astrophysics, geochemistry, fluid dynamics, and finance, for example. Other applications of RD systems arise in chemotaxis, modeling bacterial growth patterns, the process of wound healing, or the spread of cancer cells in healthy tissue to enumerate only a few such ideas in mathematical biology.

RECURRENCE

Recurrence means repetition, and this, in turn, implies the presence of two actors: the particular event that is coming back after having occurred in the past and the law prescribing how events unfold in time.

The crossing of the vertical position by a well-serviced pendulum is a recurrent event. Here the event coincides with a particular value of the position coordinate, and the intervening law is Newton's second law in the presence of gravity. We deal here with the simplest version of recurrence, namely, strict periodicity. But one could also say that in a capitalistic economy, economic growth or slow down are recurrent events. The event is now an attribute of a whole succession of outcomes interrupted by irregular periods where this attribute is absent, and the intervening laws are no longer directly reducible to nature's dispassionate fundamental interactions but involve, rather, competing human agents each one of whom wishes to maximize his profit. In a still different vein, the need for survival has made man aware of the repeated appearance (recurrence) of weather patterns associated with different winds and/or precipitation patterns. The Greeks constructed an octagonal structure, the Tower of Winds, which can still be visited in Athens. It depicts the wind from each cardinal point and comprises bas-relief figures representing the typical type of weather associated with such a wind. The event is now a lumped, coarse-grained characterization of the state of the atmosphere that came to be known later on as *Grosswetterlagen* or "atmospheric analogs," and the laws are those of fluid mechanics and thermodynamics as applied to a rotating frame.

In the physical sciences, the description usually adopted views the system of interest as a deterministic dynamical system. At first sight this entails that an event is to be associated with the point that the system occupies in phase space at a given time. But in this view exact recurrence of a state is impossible except for the trivial case of periodic dynamics, because it would

Figure 1. Illustrating recurrence on a two-dimensional projection of the Lorenz chaotic attractor. Recurrence is here reflected by the fact that the trajectory emanating from point P in the dotted square will re-enter this cell (which plays the role of a coarse-grained state) after some time.

violate the basic property of uniqueness of the solutions of the evolution equations. To cope with this limitation, one associates the concept of recurrence with repeated re-entries of the dynamical trajectory in a phase space region possessing finite volume (more technically, “measure”) as indicated in Figure 1. This is, precisely, the coarse-grained state referred to earlier, as opposed to the point-like states considered in many (or even most) nonlinear science-related problems. Probabilistic description is a typical instance in which one deals essentially with coarse-grained states.

Poincaré Recurrence

In his celebrated memoir on the three-body problem Henri Poincaré, a founding father of nonlinear science, established a result that may be considered as the first quantitative and rigorous statement concerning recurrence (Poincaré, 1890). He showed that in a system of point particles under the influence of forces depending only on the spatial coordinates, a typical phase space trajectory will visit infinitely often the neighborhood, however small, of a prescribed initial state, provided that the system remains in a bounded region of phase space. The time between two such consecutive visits is referred as a “Poincaré recurrence time.”

In modern terms (Kac, 1959), let A be a subset of space Ω within which the system is confined such that $\mu(A) > 0$ where μ designates the measure of A , and T_t a family of one-to-one measure preserving transformations in Ω . Then, for almost every initial point $P \in A$ (i.e., except for a set of P s of zero μ -measure), there exists a sufficiently large t such that

$T_t P \in A$. Using the machinery of the proof, one may derive an expression for the mean recurrence time,

$$\langle \theta_t \rangle = \tau / \mu(A), \quad (1)$$

where τ is the time resolution between the successive observations. Actually, as observed by Marian Smoluchowski, this expression needs to be adapted, in the limit of continuous time, to

$$\langle \theta_t \rangle = \tau(1 - \mu(A)) / (\mu(A) - \mu(P \in A, T_t P \in A)), \quad (2)$$

where one has introduced the measure of the intersection of A and its pre-image $T_t^{-1}A$.

Part of the historical role of Poincaré’s theorem relates to the famous *Wiederkehrwand*, an early objection by Ernst Zermelo challenging Ludwig Boltzmann’s derivation of the second law of thermodynamics on the grounds that since states recur, the H -function (the microscopic analog of entropy) is bound to reverse its course at some stage. Boltzmann made a valiant attempt to respond, based essentially on the enormity of recurrence times in a molecular system (of the order of ten to the power of the Avogadro number). A more pertinent observation is that thermodynamic states are associated with a Gibbs ensemble rather than with single phase space points. Poincaré’s theorem does not apply under these conditions; hence, Poincaré recurrences are not necessarily precluding a microscopic interpretation of irreversibility.

From Ehrenfest to Fermi–Pasta–Ulam

A first implementation of the idea that it is indeed possible to reconcile recurrence with irreversible behavior was provided by the, by now famous, “dog flea” model of Paul and Tatiana Ehrenfest. $2N$ numbered balls are distributed in boxes A and B . An integer from 1 to $2N$ is drawn at random and the ball corresponding to that number is moved from the box in which it is found to the other one. The process is then repeated to any desired number of times. One can show (Kac, 1959) that every initial state recurs with probability one, although the system possesses an H -function. Actually, this model belongs to a general class of stochastic processes known as Markov chains, whose theory was developed intensely in the first part of the 20th century (Feller, 1968, 1971). These developments allow one to put the compatibility between recurrence of states and irreversible approach to an asymptotic regime on a firm basis for this very general class of processes amenable to a Markov chain-like description. An important insight is that while recurrence is a property of trajectories (which being now stochastic and thus coarse-grained are not bound to satisfy the uniqueness theorem stated above and can therefore recur as such), the approach to an asymptotic regime is a property of

probability distributions. The theory of stochastic processes has also provided a wealth of further information on recurrence independent of the problem of irreversibility, including connections with the important class of renewal processes.

Despite their power, the above results overlooked the nature of the underlying deterministic dynamics, except that the last had to be complex enough to generate somehow a stochastic game. This shortcoming became clearly recognized in the 1950s, when Poincaré's recurrence was viewed again as a problem of strictly deterministic dynamics, thanks partly to the new possibilities afforded by the availability of electronic computers. From the standpoint of nonlinear science, the most relevant among these early attempts is that by Fermi, Pasta, and Ulam (Fermi et al., 1955) who numerically examined a set of coupled differential equations modeling the motion of a linear chain of equimass particles connected by nonlinear springs

$$\begin{aligned} \frac{d^2 x_j}{dt^2} &= \{1 + \beta[(x_{j+1} - x_j)^2 + (x_j - x_{j-1})^2 \\ &\quad + (x_{j+1} - x_j)(x_j - x_{j-1})]\} \\ &\quad \times (x_{j+1} + x_{j-1} - 2x_j), \\ j &= 1, 2, \dots, N-1, x_0 = x_N = 0. \end{aligned} \quad (3)$$

Fermi et al. showed that with 64 particles at low energy there was no equipartition of energy among the oscillators (contrary to their expectations). Instead, a beat phenomenon was observed with ongoing recurrences of initial conditions. Recurrence seemed once again to be at odds with the tendency toward thermal equilibrium, to which is associated the stronger property of mixing and equipartition. A closer analysis shows that Fermi–Pasta–Ulam recurrence is not universal: for higher energies a phenomenon of overlap of resonances is taking place, leading to stochasticity in the sense that energy transfer between modes becomes possible. To what extent this stochasticity can invade the entire phase space as N and the energy are increased is still an unsettled question.

Modern Nonlinear Dynamics and Recurrence

The most significant advance on recurrence since the 1960s has been to dissociate the concept from the approach to equilibrium of a many-body system (and, in particular, to realize that the two concepts are not to be opposed), to extend it to cover the class of dissipative dynamical systems, and to establish a link between the deterministic and the stochastic approaches to it.

What made this advance possible is the realization, at the heart of modern nonlinear dynamics, that simple-looking, low-dimensional models may give rise to complex behavior that emulates, to a large extent, the behavior of real world, multivariate systems. Furthermore, in the presence of deterministic chaos,

sensitivity to initial conditions raises the problem of long-term prediction and prompts one to adopt a probabilistic approach, perfectly compatible with (and actually induced by) the underlying dynamics, in which quantities of interest are expressed as statistical averages. In this setting, recurrence became a powerful tool providing new insights along two directions.

Recurrence as an Indicator of the Dynamical Complexity

The main point here is that dynamical systems having different ergodic properties show different recurrence patterns. An interesting example is uniform quasi-periodic motion on a two-dimensional torus or its equivalent discrete-time version given by the shift map. It can be shown (Sös, 1958; Theunissen et al., 1999) that, typically, such a system (known to be ergodic) possesses exactly three possible values of recurrence times in any prescribed phase space cell. On the other hand, in a wide class of uniformly hyperbolic systems such as one-dimensional maps, one shows that recurrence times in a sufficiently small phase space cell are generically exponentially distributed, while a sequence of successive recurrences has a Poissonian limit distribution (Collet, 1991). The situation is different in non-uniformly hyperbolic systems. In particular, in systems showing intermittent behavior the above laws are replaced, respectively, by power laws and by Lévy stable distributions (Balakrishnan et al., 1997). Work along similar lines has also led to connections between recurrence patterns and Lyapunov exponents, unstable periodic orbits, or generalized dimensions. There is, however, no firm indication about the universality of these latter results.

Recurrence as a Tool for Prediction

The question whether, and if so how frequently, the future states of a system will come close to a certain initial configuration has a direct bearing on prediction, an issue of central importance in atmospheric sciences, hydrology, and other environment-related disciplines. A dynamical approach to the recurrence of atmospheric analogs, the lumped states of the atmosphere introduced above reveals a strong dependence of recurrence times on the local properties of the attractor and a pronounced variability around their mean (Nicolis, 1998). Of crucial interest is also the recurrence of extreme events such as natural disasters, a problem approached traditionally at the level of a statistical description (Gumbel, 1958). The extension of the statistical theory of extremes and their recurrences to deterministic dynamical systems is still in its infancy.

REGULAR AND CHAOTIC DYNAMICS IN ATOMIC PHYSICS

Many important areas of atomic physics dwell in the intriguing world of semiclassical quantum mechanics, where classical concepts such as orbits and phase space are used to calculate purely quantal quantities such as quantum numbers, wave functions, and ionization thresholds. The past two decades have witnessed renewed interest in classical interpretations of quantum phenomena (Berry & Mount, 1988; Casati et al., 1987; Blümel & Reinhardt, 1997; Jensen, 1992), a view sometimes referred to as postmodern quantum mechanics (Heller & Tomsovic, 1993). This development has led to the much debated term *quantum chaos* (See **Quantum chaos**). A central issue is the relevance of chaotic dynamics to the quantum world, where the sensitivity to initial conditions characteristic of classical chaos is obscured by the Heisenberg uncertainty principle. Moreover, the Schrödinger equation is linear and does not normally exhibit extreme sensitivity to initial conditions. Nevertheless, classical dynamics plays an important role in the quantum world, even in chaotic regions. Thus, the ionization of hydrogen by a microwave field is often well described in terms of chaotic diffusion of classical electron orbits, while the quantum mechanical wave function exhibits traces of classical (unstable) periodic orbits, called scarring.

When the classical dynamics are regular, semiclassical quantum numbers can be calculated according to the Einstein–Brillouin–Keller (EBK) prescription (Gutzwiller, 1990),

$$J_i = \oint p_i dq_i = (n_i + \alpha_i/4)h, \quad (1)$$

where J_i is the classical action, calculated from the loop integral over coordinate q_i and canonically conjugate momentum p_i , n_i is the corresponding quantum number, h is Planck's constant, and α_i is the Maslov index, an integer that depends on the topology of the invariant torus. In this way, approximate semiclassical wave functions can also be constructed. The semiclassical description is found to work well under two conditions: (i) the quantum numbers are large, and (ii) the number of participating states is also large. Under chaotic conditions (when the classical action does not generally exist), one still has recourse to periodic orbits (Eckhardt, 1988), which can be used to organize energy levels and the form of the wave function (Gutzwiller, 1990). The principal tool under chaotic conditions is the Gutzwiller trace formula, based on the Feynman propagator.

Our unifying theme is the hydrogen atom in an electromagnetic field, for which the motion of the single electron is well described by a Hamiltonian model. We consider first two closely related integrable cases (See **Constants of motion and conservation laws; Integrability**), the classical problem of two fixed centers as a model for the hydrogen molecule ion H_2^+ , and the H-atom in a homogeneous electrostatic field. In both cases axial symmetry implies the constancy of the azimuthal angular momentum, $p_\phi = m\rho^2\dot{\phi}$ (in cylindrical coordinates ρ, ϕ, z), allowing a reduction in dimensionality from three to two, via an effective potential formed by including the azimuthal part of the kinetic energy with the potential $U(\rho, z)$:

$$U^e(\rho, z) = U + \frac{p_\phi^2}{2m\rho^2}. \quad (2)$$

Thus, in both cases the motion is described by a two degree of freedom autonomous (time-independent) Hamiltonian.

Next we take up the non-integrable case of the H-atom in a homogeneous magnetostatic field, which has been extensively studied, both theoretically and experimentally (Born, 1960; Friedrich & Wintgen, 1989), and which is also described by a two-degree-of-freedom Hamiltonian. Then we describe fruitful experiments on microwave ionization of H-atoms, which have yielded an abundance of information on quantum physics (Blümel & Reinhardt, 1997; Koch & van Leeuwen, 1995). Various Hamiltonian models have been investigated, from one to three degrees of freedom. Here, we shall limit ourselves to a one-dimensional time-periodic model, which captures most

of the relevant physics. Finally, we briefly mention other atomic systems in which a semiclassical treatment sheds light on quantal behavior.

Two Fixed Centers

The two fixed centers model (TC) consists of a test mass orbiting in the gravitational field of two massive bodies rotating about their center of mass at a fixed distance. In atomic physics the attractive force is electrostatic, furnishing a useful model for the hydrogen molecule-ion (Born, 1960; Strand & Reinhardt, 1979; Howard & Wilkerson, 1995). It also enjoys the distinction of being one of the small minority of completely integrable systems, owing to separability in confocal elliptic coordinates. With the two protons fixed at $z = \pm a$, the nonrelativistic motion of the electron is described by the Hamiltonian,

$$H = \frac{1}{2m}(p_\rho^2 + p_z^2) + U^e \quad (3)$$

with effective potential

$$U^e(\rho, z) = \frac{p_\phi^2}{2m\rho^2} - q^2 \left(\frac{1}{r_1} + \frac{1}{r_2} \right), \quad (4)$$

where q is the electronic charge,

$$r_1^2 = \rho^2 + (z - a)^2, \quad r_2^2 = \rho^2 + (z + a)^2, \quad (5)$$

and $p_\rho = m\dot{\rho}$, $p_z = m\dot{z}$, and $p_\phi = m\rho^2\dot{\phi}$. All trapped orbits are confined by the two-dimensional effective potential, shown in Figure 1 for two nearby values of the control parameter $\mu = p_\phi^2/a^2$. In the first case, a single well centered on an equatorial critical point of U^e exists, which in the second case has bifurcated into a double well. Quantizable stable circular orbits exist at the elliptic critical points of U^e . Because there is no chaos in this system, it might seem straightforward to construct quantum numbers from the two conserved actions, taking care to get the correct Maslov indices. However, there is a rub: there are two disjoint classes of orbits, a situation referred to as “monodromy,” resulting in separate actions, which need to be smoothly joined. This process of “uniform quantization” has been carried out by Strand & Reinhardt (1979), who obtained greatly improved values for energy levels for varying intermolecular separation $R = 2a$.

Hydrogen Atom in a Strong Electric Field

The behavior of the H-atom in a homogeneous electrostatic field is one of the oldest problems of quantum mechanics, the weak-field case giving rise to the Stark effect, traditionally treated using perturbation theory (Born, 1960). For larger fields, ionization occurs (Koch, 1978; Howard, 1995), the ionization threshold field F_c depending on the particle energy as well as a quantity called the Runge–Lenz invariant.

Figure 1. Contour plot of effective potential for the hydrogen molecule-ion before and after pitchfork bifurcation.

This is an interesting problem for two reasons: (i) the required fields are too large for perturbative methods, and (ii) the motion is completely integrable, since the Hamiltonian and the Schrödinger equations both separate in parabolic coordinates. Spectral lines are then conveniently labeled by quantum numbers n, n_1, n_2 , and $|m|$, where $n = n_1 + n_2 + |m| + 1$ is the principal quantum number, m is the azimuthal quantum number, and n_1 and n_2 are parabolic quantum numbers.

Field ionization may be treated either classically or via quantum mechanical tunneling (Gallas et al., 1982). With the electric field along the z -axis, the nonrelativistic motion of the electron is again described by Hamiltonian (3), with effective potential

$$U^e(\rho, z) = -\frac{q^2}{\sqrt{\rho^2 + z^2}} + \frac{p_\phi^2}{2m\rho^2} - qFz, \quad (6)$$

Figure 2. Electron orbit with energy $E < E_s$ trapped in effective potential for the hydrogen atom immersed in a homogeneous electric field.

where p_ϕ gives the azimuthal quantum number $m = p_\phi/\hbar$ and F is the electric field strength. Figure 2 shows an orbit trapped in the two-dimensional potential well formed by the effective potential. All orbits having $E < E_s$, the saddle point energy, are classically trapped. If the system were non-integrable, the condition $E > E_s$ would constitute a necessary and sufficient condition for ionization. However, the existence of the Runge–Lenz invariant allows a subclass of trapped orbits with $E > E_s$. Owing to separability in parabolic coordinates (ξ, η) , the actions J_ξ , J_η , and $J_\phi = p_\phi$ always exist so that the EBK formula applies; there is no classical chaos in the Stark problem. In laboratory experiments the electric field is usually gradually increased from zero until ionization occurs. For $m = 0$, the saddle point criterion leads to the ionization threshold $F_c \approx 1/9n^4$, in excellent agreement with experiment.

Hydrogen Atom in a Strong Magnetic field

In contrast to the Stark problem, the electron motion in an H-atom immersed in a homogeneous magnetostatic field can be chaotic, providing a useful testing ground for ideas of quantum chaos (Friedrich & Wintgen, 1989). There are two integrable limits, (i) $B = 0$, for which the orbits are simple Kepler ellipses, and (ii) $B \rightarrow \infty$, the helical gyration of a free charged particle in a constant magnetic field. With $B = B_0 \hat{z}$, the nonrelativistic motion of a single electron is governed by the effective potential

$$U^e(\rho, z) = \frac{p_\phi^2}{2m\rho^2} - \frac{q^2}{\sqrt{\rho^2 + z^2}} + \frac{1}{8}m\omega_c^2\rho^2 + \frac{1}{2}\omega_c p_\phi, \quad (7)$$

where $\omega_c = qB_0/mc$ is the cyclotron frequency and now $p_\phi = m\rho^2\dot{\phi} + \frac{1}{2}\rho^2\omega_c$. The constant paramagnetic

Figure 3. Poincaré section for H-atom in a uniform magnetostatic field.

term may be removed by transforming to a rotating frame. For small magnetic field strength, perturbation theory may be used to calculate energy levels (Zeeman effect); for very large fields, the diamagnetic term proportional to ρ^2 dominates (quadratic Zeeman effect) and the spectrum resembles that of a free electron. In this case, the existence of chaotic trajectories means that a set of classical actions does not always exist, precluding EBK quantization. For small fields, however, canonical perturbation theory can be employed to calculate perturbed actions. This yields useful energy level curves $E_n = E_n(B)$, where the levels are labeled in terms of the unperturbed ($B = 0$) states. Furthermore, at low fields an approximate constant of the motion exists, facilitating classification of the very complex spectrum and explaining avoided crossings of nearby energy level curves. This recipe fails for larger fields, where the classical motion is mainly chaotic. At very large fields, intriguing regularities persist, called quasi-Landau resonances, close to the spectrum of a free electron in a magnetostatic field. In this case, it is possible to derive a very simple formula for the ionization threshold energy.

The degree of classical chaos is conveniently revealed by the Poincaré section, which is a two-dimensional slice in the four-dimensional phase space, defined by fixing the total energy and recording unidirectional intersections with a coordinate plane (Lichtenberg & Lieberman, 1990). Figure 3 shows a section for a moderately large B -field, generated by calculating particle orbits and recording (ρ, p_ϕ) each time an orbit crosses the $z = 0$ plane with $p_z > 0$. Regular orbits appear as smooth closed curves, whose centers represent periodic orbits. A single period-one orbit appears near $\rho = 1.45$; all other fixed points are at least period-three. The scattered dots in between represent chaotic orbits (possibly just one), which ergodically fill a connected region of phase space. In this case, classical actions do not exist, and it is

not possible to assign quantum numbers to the very complex spectrum.

Microwave Ionization of Rydberg Atoms

Another fruitful source of information on connections between classical dynamics and quantal behavior is the extensive experimental program on microwave ionization of highly excited Rydberg (hydrogenic) atoms (Blümel & Reinhardt, 1997; Koch & van Leeuwen, 1995). By careful control of experimental conditions, it has been found possible to produce a full range of principal quantum numbers, $n_0 = 34$ to more than 90. Ionization from such excited states can then be readily accomplished using a variety of pulsed or continuous wave sources; linearly polarized, circularly polarized, or elliptically polarized. Remarkably, classical scaling accurately describes much of the experimental results. Thus, the microwave frequency is expressed as a ratio to the Kepler frequency, which according to the Bohr–Sommerfeld model is proportional to n_0^{-3} , giving the dimensionless parameter $\hat{\omega} = n_0^3 \omega$. The electric field strength may also be expressed as a ratio to the Coulomb force, giving the dimensionless parameter $\hat{F} = n_0^4 F$. Koch distinguishes several distinct frequency regimes, depending on $\hat{\omega} = n_0^3 \omega$; by fixing $\omega/2\pi$ at one of several frequencies between 7 and 36 GHz and varying n_0 , a range of scaled frequencies from $\hat{\omega} = 0.02$ to 2.8 can be achieved. For very low $\hat{\omega} \lesssim 0.02$ quantum tunneling dominates, significantly lowering the ionization threshold $\hat{F}_i$. At somewhat higher $\hat{\omega}$ the ionization curves (fraction ionized vs. $\hat{F}$) are primarily classical, with occasional “bumps” deriving from quantum resonances. For $0.1 \lesssim \hat{\omega} \lesssim 1.2$ classical dynamics prevails. Above this value quantum mechanisms increasingly raise the ionization thresholds, by about a factor of two at $\hat{\omega} = 2.8$. As for the Zeeman effect, scarring of the wave function occurs along classical unstable period orbits.

Theoretical and numerical analyses range from crude one-dimensional (1-d) models to elaborate 3-d Monte Carlo simulations. The simplest case to analyze theoretically is linear polarization, in which a simple one-dimensional time-periodic Hamiltonian explains much of the relevant physics,

$$H = H_0 + qFx \sin(\omega t), \quad (8)$$

where

$$H_0 = \begin{cases} \frac{p^2}{2m} - \frac{q^2}{x}, & x > 0, \\ \infty, & x \leq 0. \end{cases} \quad (9)$$

Physically this represents the limiting case of a pencil-thin orbit along the x -axis. In order to compare with experiment, we first transform to action-angle variables $J = \sqrt{a} = \sqrt{-1/2H_0}$, $\theta = u - \sin u$, where a is the semimajor axis and the eccentric anomaly u is defined

Figure 4. Poincaré section for 1-d H-atom perturbed by a time-periodic microwave field of frequency $f_{\text{RF}} = 9.923$ GHz and strength (a) $F = 62$ V/cm and (b) $F = 66.4$ V/cm.

by $x = a(1 - \cos u)$. The principal quantum number is then given by $J = n_0 \hbar$. Poincaré sections can be generated by strobing the orbit at a period $\tau = 2\pi/\omega$ and recording J and θ at $t = \tau, 2\tau, \dots$. In experiments the microwave field is gradually increased until ionization takes place. For example, for $f_{\text{RF}} = 9.923$ GHz, we obtain the two sections near the $n_0 = 51$ state shown in Figure 4 for $F = 62$ and 66.4 V/cm. At the lower field strength all orbits initialized with $n_0 < 51$ are trapped by invariant circles; at the higher field strength these curves have been destroyed, allowing most of the same orbits to escape. The experimental result for 10% ionization of the $n_0 = 51$ state is about 71 V/cm (Koch & van Leeuwen, 1995), in reasonable agreement with our numerical calculation. Other polarizations have also been investigated (Koch, 1998; Howard, 1992). The most general state is elliptic polarization, which includes circular and linear polarization as special cases. In all cases valuable insight into experiment has been obtained using classical dynamics.

Discussion

In addition to the above four examples, there are several other systems under active investigation. Combinations

of fields, particularly crossed and parallel fields, $\mathbf{E} \times \mathbf{B}$ and $\mathbf{E} \parallel \mathbf{B}$, offer challenging structures that can be partially explained by semiclassical quantization (Farrelly, 1991). Three-body systems, such as the helium atom (Tanner et al., 2000) and the hydrogen negative ion H^- , long considered beyond semiclassical methods, have recently yielded important insights.

RELAXATION OSCILLATORS

The first work related to relaxation oscillators was published by Balthasar van der Pol in 1926 (Van der Pol, 1926). Van der Pol, in collaboration with J. van der Mark, suggested an electrical model of the heart consisting of three relaxation generators (van der Pol & van der Mark, 1928).

An oscillator is said to be of the relaxation type if its period is inversely proportional to a relaxation time and nearly independent of other parameters. Classical examples of relaxation oscillators are a thyatron oscillator (Teodorichik, 1952) and an alternating water source known as Tantal's vessel (Panovko & Gubanova, 1964; Strelkov, 1964). Schematic images of these devices are illustrated in Figures 1a and b. The shape of oscillations of the amount of water in Tantal's vessel and of the voltage across the capacitor C is shown in Figure 1c.

An oscillator described by the Rayleigh equation (Rayleigh, 1877–78)

$$\ddot{x} - \mu(1 - \dot{x}^2)\dot{x} + x = 0 \quad (1)$$

is also of relaxation type for $\mu \gg 1$. It should be noted that the Rayleigh equation can be obtained from the van der Pol equation

$$\ddot{y} - \mu(1 - y^2)\dot{y} + y = 0 \quad (2)$$

by the substitution $y = \sqrt{3}\dot{x}$.

The phase portrait and the shape of oscillations for Equation (1) are illustrated in Figure 2 for $\mu = 10$. For this value of μ , the equilibrium state is an unstable node and the limit cycle has a shape close to a parallelogram. The time required for the representative point to approach the limit cycle is very short; thus the oscillations are almost discontinuous. For $\mu \ll 1$, the oscillation period is practically independent of μ and approximately equal to the period of free oscillations of the oscillatory circuit $T_0 = 2\pi$. For $\mu \gg 1$, on the other hand, the oscillation period is completely determined by the value of the parameter μ , namely $T \approx 8\mu/3\sqrt{3}$ (see below). As the relaxation time is of the order of $1/\mu$, it follows that for $\mu \gg 1$ the oscillation period is really inversely proportional to the relaxation time.

Introducing the small parameter $\varepsilon = 1/\mu$, we can rewrite Equation (1) in the form of two equations of

Figure 1. Schematic images (a) of a thyatron oscillator, (b) of Tantal's vessel, and (c) the shape of oscillations of the amount of water in Tantal's vessel and of the voltage across the capacitor C .

Figure 2. (a) The phase portrait for the Rayleigh equation for $\mu = 10$, and (b) the solution of this equation for $\mu = 10$: curves 1 and 2 show $x(t)$ and $\dot{x}(t)$, respectively.

first order as

$$\dot{x} = y, \quad (3)$$

$$\varepsilon \dot{y} = (1 - y^2)y - \varepsilon x. \quad (4)$$

To find an approximate solution of Equations (3) and (4) we apply the averaging method in systems incorporating fast and slow variables. It follows that the variable x is slow and the variable y is fast. Consequently, in solving Equation (4) the variable x can be considered as a constant. Stationary solutions of Equation (4) under this condition are real roots of the cubic equation

$$y^3 - y + \varepsilon x = 0. \quad (5)$$

Over the range

$$-\frac{2}{3\mu\sqrt{3}} < x < \frac{2}{3\mu\sqrt{3}} \quad (6)$$

Equation (5) has three real roots, whereas outside this range it has only one real root. For $x = \pm 2/(3\mu\sqrt{3})$ Equation (5) has two real roots, $y_1 = \pm 1/\sqrt{3}$, $y_2 = \mp 2/\sqrt{3}$. Approximate solutions of Equation (5) can be found analytically under the condition $\varepsilon x \ll 1$. Expanding y sequentially about $y_{10} = 1$, $y_{20} = -1$ and $y_{30} = 0$ we find three solutions:

$$y_1 = 1 - \frac{\mu}{2}x, \quad y_2 = -1 - \frac{\mu}{2}x, \quad y_3 = \mu x. \quad (7)$$

It is seen that the approximate solutions (7) are close to the exact ones over the range (6).

Investigation of the stability of these shows that only those solutions are stable that satisfy the constraint $y_i \geq 1/\sqrt{3}$, which is fulfilled for the upper and the lower parts of the dependence $y(x)$ and is not fulfilled for its middle part.

Substituting $y_{1,2}$ from (7) into Equation (3) and integrating the latter, we find solutions of this equation under the initial condition $x(0) = x_0$:

$$x_{1,2}(t) = x_0 e^{-\varepsilon t/2} \pm \frac{2}{\varepsilon} (1 - e^{-\varepsilon t/2}). \quad (8)$$

For $\varepsilon t \ll 1$ solutions (8) can be simplified as

$$x_{1,2}(t) = (x_0 \pm t) (1 - \varepsilon t/2). \quad (9)$$

Let the initial conditions be $x_0 = -2/(3\varepsilon\sqrt{3})$, $y_0 = y_1(x_0)$. Then, as follows from (9), x will increase with an approximately constant rate, and at the instant $t = 4/(3\varepsilon\sqrt{3})$, it will attain the value $2/(3\varepsilon\sqrt{3})$. At this instant, the solution $y_1(x)$ becomes unstable because it merges with the unstable solution $y_3(x)$. As a result, y will jump to the value $y_2(2/(3\varepsilon\sqrt{3}))$. Subsequently, x will decrease to the value $-2/(3\varepsilon\sqrt{3})$ and then a jump will occur again; that is, y will take on the value $y_1(-2/(3\varepsilon\sqrt{3}))$. As the process is repeated, we obtain a limit cycle on the phase plane x, y close to the one calculated numerically (Figure 2).

If $y_0 \neq y_{1,2}(x_0)$, y takes on one of these values very rapidly, practically for a constant x . This means that the corresponding phase trajectories are nearly vertical.

An approximate expression for the oscillation period T can be found on the assumption that the jumps occur instantly and x varies with the constant velocity ± 1 . Thus

$$T \approx \frac{8}{3\varepsilon\sqrt{3}} = \frac{4}{3\pi\sqrt{3}} \mu T_0, \quad (10)$$

where $T_0 = 2\pi$ is the period of natural oscillations for $\mu = 0$. Thus, in the relaxation regime, the oscillation period is approximately $\mu/4$ times the period of natural oscillations.

Importantly, one of the characteristic features of relaxation oscillators is the ease of frequency synchronization (Landa, 2001). This phenomenon was apparently first studied by Teodorichik (1943, 1945). Relaxation oscillators have long been used in radio and electrical engineering, mainly as multivibrators, but recently interest in these oscillators has quickened in connection with biological and medical applications. As early as 1953, the German physicist Karl Bonhoeffer suggested that a neuron might be modeled by equations similar to the van der Pol equation for a relaxation oscillator. The Bonhoeffer-van der Pol

equations describe oscillations of the voltage across a neural membrane, including refractoriness (difficulty of refiring). These equations are

$$\dot{x} = x - x^3/3 - y + I_0, \quad \dot{y} = \varepsilon(x + a - by), \quad (11)$$

where x is the voltage across the neural membrane; y is a quantity of refractoriness; a, b, ε are membrane radius, specific resistivity of the fluid inside the membrane, and temperature factor, respectively; and I_0 is a direct component of the current across the membrane.

RENORMALIZATION GROUPS

Systems undergoing phase transitions at a critical temperature T_c are conveniently described in terms of order parameters and critical exponents. Above T_c , for example, the specific heat is found experimentally to vary as $\varepsilon^{-\alpha}$ where $\varepsilon \equiv (T - T_c)/T_c$, and below T_c , it varies as $(-\varepsilon)^{-\alpha'}$. Thus, α and α' are called critical exponents for specific heat. Similar critical exponents are found for order parameters, isothermal susceptibility, response to an external field, the correlation length ξ , and the pair correlation function $\Gamma(r)$. These are denoted as $\beta, \gamma, \delta, \nu$, and η , respectively.

Relations among these critical exponents can be derived from scaling assumptions such as the static scaling hypothesis, which asserts that the Gibbs

potential $G(T, H)$ for magnetic systems (as an example) is a generalized homogeneous function

$$G(\lambda a_\varepsilon, \lambda^{a_H} H) = \lambda G(\varepsilon, H). \quad (1)$$

With an arbitrary value of λ and selecting a_ε, a_H appropriately, relations among critical exponents are found through thermodynamic identities, for example, $M(\varepsilon, H) = -dG(\varepsilon, H)/dH$. Thus, Equation (1) leads to the following relations:

$$\begin{aligned} \beta &= \frac{1 - a_H}{a_\varepsilon}, \quad \delta = \frac{a_H}{1 - a_H}, \quad \gamma' = \frac{2a_H - 1}{a_\varepsilon}, \\ \gamma &= \frac{2a_H - 1}{a_\varepsilon}, \quad \alpha' = 2 - \frac{1}{a_\varepsilon}. \end{aligned} \quad (2)$$

These can be recast as critical exponent equations:

$$\begin{aligned} \alpha + \beta(\delta + 1) &= 2, \\ \alpha' + 2\beta + \gamma' &= 2, \\ \gamma(\delta + 1) &= (2 - \alpha)(\delta - 1), \\ \gamma' &= \beta(\delta - 1), \\ \gamma &= \gamma', \\ \alpha &= \alpha', \end{aligned}$$

reducing the number of independent critical exponents to just four (a_ε, a_H, ν , and η).

The two exponents that describe spatial correlations (ν and η) also involve a scaling relationship as was shown through dynamic scaling arguments by Leo Kadanoff and Michael Fisher, among others. In the two-dimensional (2-d) Ising model above T_c , for example, spin-spin correlations show short-range order, whereas below T_c , the system exhibits long-range order. As T tends to T_c from either side, $\Gamma(r - r')$ becomes long ranged and decays slowly as $|r - r'| \gg 1$, with the correlation length diverging. This is typical of most critical systems for which long-range fluctuations accompany the onset of a second-order phase transition. However, in the 2-d XY model, the correlation function exhibits an algebraic fall-off as $\Gamma(r) \sim r^{-\eta(T)}$, demonstrating lack of long-range order in an unusual critical system—the so-called Kosterlitz–Thouless transition whose hallmark is the formation of vortex-antivortex pairs. Mermin and Wagner (1966) proved that any 2-d system with short-range interactions whose ordered phase has a continuous symmetry does *not* support long-range order. This is because at least one branch of collective excitations—called Goldstone bosons—has energy that tends to zero continuously as its wave vector (crystal momentum) vanishes.

With the exception of such unusual systems, spatial scaling applies to criticality, which according to Kadanoff is to be understood as coarse graining. This means that the essential features of the system remain

unchanged as the lattice length scale is increased by a factor λ such that $1 \ll \lambda \ll \xi/a$, where ξ is the correlation length and a is the lattice spacing (see Figure 1).

If N is the number of lattice sites and d the dimensionality of the system, then $m = N/\lambda^d$ is the number of blocks obtained in the first rescaling process. Simultaneously, the lattice variables (e.g., spins) and the interaction parameters are redefined. The effective spins now represent each block and interaction parameters refer to the interacting blocks. Taking the Ising model as an example, the cell Hamiltonian is

$$H_{\text{cell}} = -J \sum_{(i,j)} S_i S_j - h \sum_i S_i. \tag{3}$$

Then the block Hamiltonian becomes

$$H_{\text{block}} = -\tilde{J} \sum_{(\alpha,\beta)} \tilde{S}_\alpha \tilde{S}_\beta - \tilde{h} \sum_\alpha \tilde{S}_\alpha, \tag{4}$$

where the tilde quantities refer to blocks. Crucial assumptions are that thermodynamic potentials scale

Figure 1. A schematic illustration of the Kadanoff construction.

with block size as

$$F_{\text{block}}(\tilde{\varepsilon}, \tilde{h}) = \lambda^d F_{\text{cell}}(\varepsilon, h), \tag{5}$$

where $\tilde{h} = \lambda^x h$, $\tilde{\varepsilon} = \lambda^y \varepsilon$, and F is a homogeneous function. Hence the exponents x and y are calculated as $y = a_\varepsilon d$ and $x = a_H d$. The Kadanoff construction applied to the pair correlation function,

$$\Gamma(i, j, \varepsilon) = \langle (S_i - \langle S \rangle)(S_j - \langle S \rangle) \rangle, \tag{6}$$

gives $y = \nu^{-1}$, and since $y = da_\varepsilon$ and $a_\varepsilon = (2 - \alpha')^{-1}$, we find that: $\alpha = \alpha'$ and $d\nu = 2 - \alpha$. Using $x = a_H d$ with $a_H = \delta/(\delta + 1)$ results in $(2 - \mu)\nu = \delta$.

Thus, static and dynamic scaling hypotheses reduce the number of independent critical exponents to just two. The renormalization group (RG) theory was developed to calculate the values of these exponents for particular models by carrying out the scaling procedure up to ξ , and because $\xi \rightarrow \infty$ as $T \rightarrow T_c$, scaling should continue “ad infinitum” as T approaches T_c .

Denoting the cell Hamiltonian by H_0 and the Hamiltonian after the n th step of rescaling as H_n , the chain of scaling transformations R is

$$\begin{aligned} R(H_0) &= H_1, \quad R(H_1) = H_2, \dots, R(H_n) \\ &= H_{n+1}, \dots, R(H^*) = H^*, \end{aligned} \tag{7}$$

where H^* denotes a fixed point Hamiltonian characteristic of the critical state. Each step in the RG transformation chain reduces the number of degrees of freedom by λ^d . In statistical mechanics, we need to ensure that the partition function retains the same symmetry and ground-state, and hence we must re-scale the coupling constant at each step, for example, $K = J/kT$ in the Ising model. We then develop a recursion relation to compute the partition function.

Model	α	β	γ	ν	δ	η

Table 1. Summary of critical exponents for key models. Note that $\varepsilon = (4 - d)$.

An iterative solution of this recursion relation for the partition function yields “roots” or fixed points that correspond to resultant critical behaviors in the model. The partition function is preserved in the RG procedure via the condition

$$Z_N(H_n) = Z_m(H_{n+1}), \quad (8)$$

where $m = N/\lambda^d$.

It is conjectured that the values of critical exponents are characteristics not of individual Hamiltonians but their sets, with numerous models leading to the same fixed point. The universality hypothesis states that any two physical systems with the same dimensionality, d , and the same number of order parameter components, n , belong to the same universality class, and each fixed point corresponds to one universality class. Table 1 is a summary of the critical exponent values obtained from RG calculations for key theoretical models.

RG ideas extend into many areas of physics, chemistry, biology, and engineering. Based on the work of Kadanoff, Kenneth Wilson proposed an algorithmic approach to the scaling problem by formulating it in reciprocal space. Although less intuitive than the real-space RG of Kadanoff, it leads to exact results for the removal of divergencies in theories of elementary particles. For this work, Wilson was awarded the 1982 Nobel Prize in Physics.

REYNOLDS NUMBER

See Fluid dynamics

RHEOLOGY

Rheology is the study of the deformation and flow of materials in general, although most real applications relate to liquids (Barnes, 2000). Deformation and flow processes are linear with respect to extent and rate of deformation only in a limited number of circumstances, and most of the liquids usually considered in practical rheology show strong nonlinear effects in typical deformation and flow situations.

Newtonian Liquids

The simplest flow behavior is that of Newtonian liquids where the viscosity, ν , is a function only of temperature and pressure, and not of the flow conditions (although the dependencies of viscosity on the pressure and temperature are themselves very nonlinear). In simple shear flow (Barnes, 2000), the behavior at any point can be adequately described by the linear equation $\sigma = \nu \dot{\gamma}$, where σ is the shear stress and $\dot{\gamma}$ is the shear rate, or velocity gradient. However, nonlinearities soon set in for the flow of low-viscosity liquids such as water, even at low flow rates. First, smooth, streamline flow is augmented by secondary flows, but these eventually give way to chaotic turbulent flow at higher flow rates. The governing factor for the onset of secondary and turbulent flows is the effect of fluid inertia, arising from the fluid's density. The ratio of inertial to viscous forces is the Reynolds number, Re , and this parameter is important for all fluid flows, whether they are Newtonian or otherwise.

Secondary flows often appear in simple flow geometries such as viscometers and are manifested as an apparent increase in viscosity, due to the extra energy dissipated in the secondary flows cells (Barnes, 2000) (see Figure 1).

The resulting increased couple in the inertial case, T_i , for a cone-and-plate instrument, compared with that for no inertia T , is given for Newtonian liquids by

$$\frac{T_i}{T} \approx 1 + \frac{6}{10^4} \left(\frac{\rho \omega^2 a^2}{\nu} \right)^2, \quad (1)$$

where ρ is the density of the liquid of viscosity ν and a is the cone radius whose angle in radians is θ . From this equation it is easy to see that the correction

Figure 2. Viscosity (in pascal-seconds) vs. shear rate (1/seconds) for (a) a range of silicone oils, and (b) 3% by weight polystyrene in toluene.

becomes important when $\rho\omega\theta^2a^2/\nu$ —which is a form of Reynolds number—exceeds 10.

Turbulent flow ensues in pipe flow when the Reynolds number given by $\rho dV/\nu$ (where V is the average velocity in a pipe of diameter d) is well above 2000, and then the pressure drop is no longer a linear function of the flow rate but approaches a quadratic dependence.

Non-Newtonian Liquids

The independence of viscosity to flow conditions is no longer valid for non-Newtonian liquids, but because their microstructure changes with the flow environment, the shear stress shows a nonlinear dependence on the shear rate. The dependence of viscosity on shear rate is such that the typical behavior is a decrease of viscosity with increase in shear rate from a value ν_0 at low shear rates, to a much lower value ν_∞ at much higher shear rates. This can often be described by the nonlinear Cross-type function

$$\frac{\nu - \nu_\infty}{\nu_0 - \nu_\infty} = \frac{1}{1 + (K\dot{\gamma})^m}, \quad (2)$$

where (written in this particular way) K has the dimensions of time and m is dimensionless. When this model is used to describe non-Newtonian liquids, the degree to which the viscosity decreases with shear rate is dictated by the value of m , with m tending to zero describing more Newtonian liquids, while the most “shear-thinning” liquids have values of m tending to unity. Figure 2 shows the departure from linearity for a number of non-Newtonian liquids.

Viscoelasticity

As well as the nonlinear behavior of viscosity, non-Newtonian liquids also display extra forces. These arise either as time or frequency effects in the linear region of behavior and are manifested, for instance, as an elastic component called the storage modulus G' in oscillatory flow as well as the viscous behavior as G'' . In the simplest form of viscoelastic liquid, the parameters G' and G'' are related by a relaxation time, λ , of the liquid. These parameters are only constant over a limited region, but for deformations greater than

Figure 3. Storage modulus (G') and viscous behavior (G'') (in Pa) vs. Oscillatory frequency (1/s) for (a) low molecular weight polyethylene melt at 150°C, and (b) commercial ketchup.

Figure 4. The shear stress (Pa) and first normal-stress difference (1st NSD) N_1 (Pa) as a function of shear rate (1/s) for a 0.5% hydroxyethyl cellulose aqueous solution.

a few percent for most non-Newtonian liquids, we enter the nonlinear region. The behavior of these G' and G'' with frequency is shown in Figure 3, along with typical departure from linearity.

For steady flows of viscoelastic liquids, the extra forces that become important are the so-called normal stresses. These arise essentially because the microstructure has a preferred configuration, which can become aligned by the flow. These normal forces manifest themselves in the linear region of slow flow as forces proportional to the square of the shear rate, but they also soon show nonlinear behavior in the region where the viscosity also becomes nonlinear. Figure 4 shows the typical behavior of both the shear stress and the first normal stress difference for a viscoelastic liquid.

Rheology of Polymeric Liquids

The microstructure that dictates the behavior of polymeric liquids is usually the state of entanglement of the polymeric chains. The chains are in incessant motion due to Brownian thermal energy, and their motions among each other give rise to viscous and elastic effects. However, as the shear rate increases, there is a gradual loss of entanglements and development of alignment, so that at high enough shear rates, linear polymer coils are transformed into aligned strings. The consequences of this change in microstructure are some very startling viscoelastic effects (Barnes, 2000).

Rheology of Suspensions

Suspension rheology depends on the relative disposition of particles relative to one another. Sometimes the particles are flocculated, and these flocs break down in size as the shear rate increases. This nonlinear phenomena can give rise to apparent yield stresses, where the viscosity is very high at low shear rates, but drops dramatically over a narrow range of stress.

Theoretical Rheology

The aim of mathematicians working in this area is to capture these complicated, and usually nonlinear, physical phenomena in constitutive equations (CEs). At their best, these describe nonlinear behaviour in viscosity—as above with the Cross-type equations—but also in the viscoelastic areas. CEs are written in the form of either differential or integral equations (see Barnes et al., 1989). A typical example of a nonlinear differential-type equation is the White–Metzner equation, where the rate-dependent viscosity $\nu_s(I I_D)$ and the relaxation time $\lambda(I I_D) I$ are written as

$$\begin{aligned} \nu_s(I I_D) &= \frac{\nu_0}{[1 + (K_1 I I_D)^n]} \\ \text{and} \\ \lambda(I I_D) &= \frac{\lambda_0}{[1 + K_2 I I_D]}, \end{aligned} \quad (3)$$

where K_1 and K_2 are parameters with the dimensions of time, n is a numerical constant, and $I I_D$ is the second invariant of the deformation tensor (Barnes & Roberts, 1992). Barnes & Roberts (1992) have shown that this type of equation can describe many nonlinear rheological situations.

RICCATI EQUATIONS

Count Jacopo Francesco Riccati (1676–1754) was an Italian nobleman who spent most of his life in the little town of Castelfranco, Veneto. Born in Venice and schooled at a Jesuit college in Brescia, he proceeded to the University of Padua where he read law. However, following his natural inclination and talent, he also took mathematical courses at Padua, and befriended Father

Stefano degli Angeli, an astronomy lecturer. Angeli introduced him to Newton's *Principia*, which they read and studied together.

Dedicated to intellectual inquiry of every sort, Riccati is mostly remembered for his significant results in mathematics, particularly separation of variables and other solution methods for ordinary differential equations. He wrote extensively on such diverse areas as physics, architecture, and philosophy. Preferring to remain in Castelfranco, where he served as mayor for several years, he turned down numerous academic offers, including an invitation from Peter the Great to become President of the St. Petersburg Academy of Science.

Throughout his life he maintained an active correspondence with Italian scholars such as Agnesi and Rizzetti, as well as with European mathematicians such as the Bernoullis. In a letter of 1720 addressed to Rizzetti, he introduced two new differential equations, which in modern notation would be written

$$\frac{dy}{dx} = ay^2 + bx^m, \quad \frac{dy}{dx} = \alpha y^2 + \beta x + \gamma x^2, \quad (1)$$

where a, b, m and α, β, γ are constants. His first published results on such equations appeared four years later (Riccati, 1724), and this paper is reproduced in Bittanti (1989) along with later related work of Euler and Liouville. Michieli's biographical work (Michieli, 1943) includes a detailed bibliography of Riccati's publications, letters, and manuscripts.

The scalar first order differential equation that today bears Riccati's name takes the general form

$$\frac{dy}{dx} = A(x)y^2 + B(x)y + C(x), \quad (2)$$

where $A \neq 0$, B, C are arbitrary functions of x . Thus, Equations (1) correspond to special cases of the Riccati equation (2) with constant A , zero B , and particular choices of C . There are two main solution methods (Ince, 1926). First, supposing that a particular solution y_1 is known, the general solution of (2) is found by the substitution

$$y = y_1 + \frac{1}{u}, \quad (3)$$

which yields the linear equation

$$\frac{du}{dx} + (2y_1 A + B)u + A = 0$$

for u . Hence u is found by quadratures, and then y is obtained (3) in terms of y_1 and u . The second method involves the substitution

$$y = -\frac{1}{A} \frac{d}{dx} \log \psi, \quad (4)$$

which transforms the Riccati equation to a homogeneous second-order linear equation for ψ , namely,

$$\frac{d^2 \psi}{dx^2} + f(x) \frac{d\psi}{dx} + g(x) \psi = 0 \quad (5)$$

with

$$f = -B - \frac{d}{dx} \log A, \quad g = AC.$$

The scalar- second order Equation (5) can be converted to a 2×2 matrix linear system of the form

$$\frac{d}{dx} \begin{pmatrix} \psi_1 \\ \psi_2 \end{pmatrix} = \begin{pmatrix} M_{11} & M_{12} \\ M_{21} & M_{22} \end{pmatrix} \begin{pmatrix} \psi_1 \\ \psi_2 \end{pmatrix}. \quad (6)$$

Riccati himself considered such a system as describing the trajectory of a point (ψ_1, ψ_2) in the plane. Requesting the equation satisfied by the slope

$$y = \frac{\psi_2}{\psi_1}, \quad (7)$$

he found the answer was precisely (2) with

$$A = -M_{12}, \quad B = M_{22} - M_{11}, \quad C = M_{21}.$$

The left action of the matrix group $SL(2)$ on the linear system (6) induces a corresponding action via Möbius transformations on the projective coordinate y . This generalizes to N th-order projective Riccati systems with nonlinear superposition principles (Anderson, 1980; Shnider & Winternitz, 1984). The latter are solved in terms of $(N+1)$ th-order linear systems, with a projective action of $SL(N+1)$.

Due to this link with linear systems, (coupled) Riccati equations naturally appear in the theory of soliton-bearing integrable partial differential equations (Fordy, 1990). Within the framework of the inverse scattering method, nonlinear soliton equations (in $1+1$ dimensions) arise as the compatibility condition for a pair of matrix linear systems,

$$\Psi_x = U\Psi, \quad \Psi_t = V\Psi. \quad (8)$$

Without loss of generality the matrices U, V are taken as $sl(N+1)$ valued functions of the dependent variables and their derivatives as well as a spectral parameter, λ , say, and subscripts denote partial derivatives.

In the simplest case, $N=1$, we consider the standard example of the Korteweg-de Vries (KdV) equation, with the first matrix in (8) given by

$$U = \begin{pmatrix} 0 & 1 \\ \lambda - u & 0 \end{pmatrix},$$

and the spatial (x) part of pair (8) is just a 2×2 system (6). The corresponding scalar equation (5) reduces to the Schrödinger equation with potential u and spectral parameter λ ; that is,

$$\psi_{xx} + u\psi = \lambda\psi,$$

and in terms of the projective variable y this yields the Riccati equation

$$y_x = -y^2 + \lambda - u. \quad (9)$$

In the special case of zero eigenvalue ($\lambda=0$), with $y=v$ formula (9) becomes the Miura map

$$u = -v_x - v^2$$

relating a solution u of the KdV equation to a solution v of the modified KdV equation. Riccati equations are further distinguished in the theory of integrable systems by the fact that (for analytic A, B, C) they are the only first-order equations with the Painlevé property (Ince, 1926).

The fundamental problem of the calculus of variations (Gel'fand & Fomin, 1963) is to extremize a functional

$$S[q] = \int_{x_0}^{x_1} L(x, q, \dot{q}) dx, \quad \dot{q} \equiv \frac{dq}{dx}, \quad (10)$$

subject to $q(x_0) = q_0, q(x_1) = q_1$. Under an arbitrary small change $h(x)$ in $q(x)$,

$$q \rightarrow q + h,$$

with $h(x_0) = h(x_1) = 0$, for a scalar function q the requirement $\delta S[h] = 0$ leads to the Euler-Lagrange equation

$$L_q - \frac{d}{dx} L_{\dot{q}} \equiv \frac{\partial L}{\partial q} - \frac{d}{dx} \frac{\partial L}{\partial \dot{q}} = 0.$$

If we further require to minimize the functional S , then a necessary condition is that the second variation should be nonnegative, that is,

$$\delta^2 S[h] = \frac{1}{2} \int_{x_0}^{x_1} (L_{\dot{q}\dot{q}} \dot{h}^2 + 2L_{q\dot{q}} h \dot{h} + L_{qq} h^2) dx \geq 0.$$

After an integration by parts, this takes the form

$$\delta^2 S[h] = \int_{x_0}^{x_1} (P \dot{h}^2 + Q h^2) dx, \quad (11)$$

where

$$P = \frac{1}{2} L_{\dot{q}\dot{q}}, \quad Q = \frac{1}{2} \left(L_{qq} - \frac{d}{dx} L_{q\dot{q}} \right).$$

Since h vanishes at the endpoints, there is the freedom to add any function of the form

$$\frac{d}{dx} (wh^2)$$

to the integrand in (11). If w is chosen to satisfy the Riccati equation

$$\frac{dw}{dx} = \frac{w^2}{P} - Q, \quad (12)$$

then the integrand for the second variation can be written in terms of a perfect square,

$$\delta^2 S[h] = \int_{x_0}^{x_1} P \left(\dot{h} + \frac{wh}{P} \right)^2 dx.$$

Thus, to ensure nonnegativity of $\delta^2 S$, we arrive at Legendre's necessary condition

$$P(x) \geq 0, \quad x \in [x_0, x_1],$$

for a minimum of the functional $S[q]$. However, some care is needed to make this argument rigorous, since the Riccati equation (12) may not have a solution on the whole interval $[x_0, x_1]$.

In the case where q has n components, $q = (q^1, q^2, \dots, q^n)$, the analogue of (12) is the matrix Riccati equation

$$\dot{W} = WP^{-1}W - Q,$$

where W , P , Q are symmetric matrices. Matrix Riccati equations are treated extensively in Reid (1972), and together with their discrete versions they find important applications in optimal filtering and control (Bittanti et al., 1991; Zelikin, 2000).

An n -component example is provided by the geodesics on a (pseudo-)Riemannian n -manifold with metric g_{jk} (Hughston & Tod, 1990), derived from the action

$$S[q] = \int_{\tau_0}^{\tau_1} g_{jk}(q) \dot{q}^j \dot{q}^k d\tau$$

with affine parameter τ along the geodesics. The Euler–Lagrange equations for the geodesics, giving the trajectories of free particle motion, are

$$\frac{d^2 q^j}{d\tau^2} + \Gamma_{kl}^j \frac{dq^k}{d\tau} \frac{dq^l}{d\tau} = 0,$$

where Γ_{kl}^j are the Christoffel symbols. In the case of a Riemannian manifold, the metric tensor is positive definite and the Legendre condition is satisfied. The geodesics are the paths of minimum length.

RIEMANN–HILBERT PROBLEM

We begin by defining what is meant by a Riemann–Hilbert problem (RHP). Let Σ be an oriented contour in $\mathbb{C}$.

By convention, if we move along the contour in the direction of the orientation, we say that the $(+/-)$ side lies to the (left/right), as indicated in Figure 1. A map v from Σ to the space of the invertible $k \times k$ matrices with complex entries is called a *jump matrix* for Σ if v and v^{-1} are bounded on Σ . We say that a

Figure 1. The contour Σ .

$j \times k$ matrix-valued function $m = m(z)$ is a *solution* of the RHP (Σ, v) if

- m is analytic in $\mathbb{C} \setminus \Sigma$,
- $m_+(z) = m_-(z)v(z)$ for $z \in \Sigma$, where $m_{\pm}(z) = \lim_{z' \in (\pm)\text{-side of } \Sigma} m(z')$.

If in addition $j = k$ and

- $m(z) \rightarrow I$ as $z \rightarrow z_0$ for some $z_0 \in \mathbb{C} \cup \{\infty\}$, we say that the RHP is *normalized* at z_0 .

A discussion of technical restrictions on Σ , and the precise sense in which the boundary values, as well as the limit at z_0 in the normalized case, are attained, can be found in many texts (see, e.g., Clancey & Gohberg (1981) and the references therein). Many problems in pure and applied mathematics, and also theoretical physics, can be expressed in terms of an RHP. Riemann–Hilbert problems are closely related to the Wiener–Hopf method. We refer the reader to Clancey & Gohberg (1981) for a history of RHPs and also to the classic text by Muskhelishvili (1946). The goal of this article is to describe some recent developments.

Remark. Included in David Hilbert’s famous list of 23 problems, was the following:

Show that there always exists a linear differential equation of the Fuchsian class with given singularities and a given monodromy group.

A Fuchsian system is an n th-order, linear system of the form

$$dm/dz = A(z)m,$$

where A is an $n \times n$ matrix with entries that are analytic except at a finite number of simple poles. Roughly speaking, the monodromy group is the group of transformations of solutions to the above Fuchsian system under analytic continuation about these poles.

The above monodromy problem turns out to be a special case of a Riemann–Hilbert problem with jump matrices that are (essentially) piece-wise constant. In the mathematical literature, the monodromy problem is sometimes identified with the Riemann–Hilbert problem, but this is incorrect. The work of Bernhard Riemann, and later of David Hilbert, on such problems, predates Hilbert’s monodromy problem and has very different origins.

Our point of departure here is the observation of Alexey Shabat in 1976 that the inverse scattering method for the Schrödinger operator can be rephrased as a RHP (see Faddeev & Takhtajan, 1987). By way of illustration, we apply Shabat’s observation to a simpler case, the self-adjoint ZS–AKNS scattering problem (Zakharov & Shabat, 1971; Ablowitz et al., 1974)

$$\frac{d\psi}{dx} = \left(iz\sigma + \begin{pmatrix} 0 & q(x) \\ \bar{q}(x) & 0 \end{pmatrix} \right) \psi, \quad (1)$$

where $\sigma = \begin{pmatrix} 1/2 & 0 \\ 0 & -1/2 \end{pmatrix}$ and $q(x)$ is a given function on $\mathbb{R}$, which decays sufficiently fast as $|x| \rightarrow \infty$. For fixed $z \in \mathbb{C} \setminus \mathbb{R}$, one seeks so-called Beals–Coifman solutions $\psi = \psi(x, z; q)$ of (1) with the properties

$$\psi e^{-ixz\sigma} \rightarrow I \text{ as } x \rightarrow -\infty, \quad (2)$$

$$\psi e^{-ixz\sigma} \text{ is bounded as } x \rightarrow +\infty. \quad (3)$$

It turns out, conversely, that for fixed $x \in \mathbb{R}$, $m(z) = m(x, z; q) \equiv \psi(x, z; q)e^{-ixz\sigma}$ solves the RHP $(\Sigma = \mathbb{R}, v_x)$ normalized at $z_0 = \infty$, where

$$v_x(z) = \begin{pmatrix} 1 - |r(z)|^2 & r(z)e^{ixz} \\ -\bar{r}(z)e^{-ixz} & 1 \end{pmatrix}, \quad z \in \mathbb{R} \quad (4)$$

and $r(z) = r(z; q)$ is the *reflection coefficient* for q . Define the *reflection map* $\mathcal{R}$ via $\mathcal{R}(q) \equiv r$. Given q , the direct scattering problem is given by

$$q \mapsto m(x, z; q) \mapsto v_x \mapsto r = \mathcal{R}(q).$$

On the other hand, for a given r and a fixed $x \in \mathbb{R}$, let $m = m(x, z; r)$ be the solution of the RHP $(\mathbb{R}, v_x)$ normalized at ∞ . Expand $m(z)$ as $z \rightarrow \infty$,

$$m(z) = I + m_1(x; r)/z + O(z^{-2}), \quad (5)$$

and define

$$(Q(r))(x) \equiv -i(m_1(x; r))_{12}. \quad (6)$$

Given r , the inverse scattering problem is given by

$$r \mapsto v_x \mapsto m(x, z; r) \mapsto m_1(x; r) \mapsto Q(r).$$

The basic analytical result in the subject is that $\mathcal{R}$ is bijective from a suitable space of q ’s onto a suitable space of r ’s (Beals & Coifman, 1984; Zhou, 1998) and that Q is the inverse of $\mathcal{R}$.

In terms of the classical method of scattering and inverse scattering (Zakharov & Shabat, 1971; Ablowitz et al., 1974), $r \equiv r(z; q)$ is the standard reflection coefficient. Moreover, if m solves the RHP (Σ, v_x) , then the Fourier transform of the first row of $m_- \begin{pmatrix} 1 & re^{ixz} \\ 0 & 1 \end{pmatrix} - I$ gives the solution of the Faddeev–Marchenko equation.

In the case of the non-self-adjoint ZS–AKNS scattering problem, the Beals–Coifman solutions $\psi(z)$ may have singularities at points $\{z_j\} \subset \mathbb{C} \setminus \mathbb{R}$, which correspond to eigenvalues with square integrable eigenfunctions. In addition, there may be singularities for $\psi_{\pm}(z)$ on the contour $\Sigma = \mathbb{R}$. One now associates an RHP to the scattering problem by augmenting the contour $\Sigma \rightarrow \Sigma_{\text{aug}}$ so as to enclose these singularities: information about the singularities is then contained in the augmented jump matrix v_{aug} defined on $\Sigma_{\text{aug}} \setminus \Sigma$ (see Zhou, 1989). The above ideas apply to very general first-order systems of size $N \times N$ and also

to differential operators of order M . The underlying contour Σ is now more complicated and may have points of self-intersection, which leads in turn to significant new technical complications. Also, the singularities of ψ in $\mathbb{C} \setminus \Sigma$ need not correspond to eigenvalues with square integrable eigenfunctions.

We now consider the relation of RHPs to the theory of integrable systems. Again by the way of illustration, we consider the normalized RHP $(\mathbb{R}, v_x)$ associated with the self-adjoint ZS–AKNS system. If $q(t) = q(x, t)$ solves the defocusing nonlinear Schrödinger (NLS) equation

$$iq_t + q_{xx} - 2|q|^2 q = 0, \\ q(x, t = 0) = q_0(x) \rightarrow 0 \text{ as } |x| \rightarrow \infty, \quad (7)$$

then by Zakharov & Shabat (1971)

$$r(t, z) = r(z)e^{-iz^2}, \quad z \in \mathbb{R}. \quad (8)$$

This leads to the following solution procedure for NLS. Let $m(x, z; r(\diamond)e^{-ir\Diamond^2}) = I + m_1(x; r(\diamond)e^{-ir\Diamond^2})z^{-1} + O(z^{-2})$ be the solution of the normalized RHP $(\mathbb{R}, v_\theta)$, where

$$v_\theta(z) = \begin{pmatrix} 1 - |r(z)|^2 & r e^{i\theta} \\ -\bar{r} e^{-i\theta} & 1 \end{pmatrix}, \quad \theta = xz - tz^2. \quad (9)$$

Then

$$q(x, t) = -i(m_1(x; r(\diamond)e^{-ir\Diamond^2}))_{12}. \quad (10)$$

An extraordinarily broad spectrum of problems, both dynamical and nondynamical, can be solved via a RHP as in (10) above. The list includes, in particular, the Painlevé equations (see Flaschka & Newell, 1980; Jimbo et al., 1981) where the underlying contour may be a union of intersecting lines, and also the orthogonal polynomial problem as formulated by Fokas, Its, and Kitaev, and the theory of Hankel and Toeplitz determinants (see e.g., Deift, 1999). In practice, RHPs often arise via associated *integrable operators* (Its et al., 1990; see also Deift, 1999). Let Σ be an oriented contour in $\mathbb{C}$. We say that an operator K acting in $L^p(\Sigma)$, $1 < p < \infty$, is integrable if it has a kernel of the form

$$K(z, z') = (z - z')^{-1} \sum_{j=1}^k f_j(z) g_j(z'), \quad z, z' \in \Sigma.$$

Special examples of integrable operators began to appear in field theory and in statistical mechanics in the late 1960s and 1970s, particularly in the work of Wu, McCoy, Tracy, and Baruch, and later Sato, Miwa, and Jimbo, but integrable operators as a distinguished class were first identified by Its et al. (1990) and later Sato–Miwa–Jimbo. Some general results on integrable operators were obtained by Lev A. Sakhnovich in the late 1960s, but the full theory of integrable operators is due to Its et al. (1990).

Integrable operators have many remarkable properties, the most important being that if $(1 - K)^{-1} = I + R$, then R is also an integrable operator, $R(z, z') = (z - z')^{-1} \sum_{j=1}^k F_j(z) G_j(z')$, and F_j, G_j can be constructed by solving an RHP $(\Sigma, v_{f,g})$ naturally associated with f_j, g_j . It turns out that many quantities H of physical interest can be expressed in the form $H = \det(1 - K)$, where K is an integrable operator. For example, let K_x be the operator acting on $L^2(0, 1)$ with kernel $\frac{\sin \pi x(z - z')}{\pi(z - z')}$, $z, z' \in (0, 1)$. Then $H_x = \det(1 - K_x)$ is the probability that in the bulk scaling limit, a Hermitian matrix chosen from the Gaussian Unitary Ensemble has no eigenvalues in $[0, x]$. Differentiating with respect to x , one derives an expression for $\frac{d}{dx} \log H_x$ in terms of $R_x = (1 - K_x)^{-1} - 1$, and hence we see that the analysis of H_x reduces to the analysis of an RHP. Similar examples arise in many different scientific areas, including statistical mechanics, percolation theory, combinatorics, representation theory of large groups, and approximation theory. Relatively recent bibliographies can be found in Deift et al. (1993, 1999).

Returning to the NLS equation, one expects from (9) and (10) that the leading order contribution to the solution $q(x, t)$ as $t \rightarrow \infty$ should arise from the stationary phase point $z_0 = x/2t$, $\theta'(z_0) = 0$, as in the classical steepest-descent method for the asymptotic evaluation of (scalar) integrals. In Deift & Zhou (1993), the authors introduce a general noncommutative steepest-descent method to analyze such microlocal problems in the context of RHPs. In the case of NLS, the method proceeds as follows (Deift, Its & Zhou, 1997; Deift & Zhou, 1994). Let δ solve the scalar RHP $((-\infty, z_0), 1 - |r|^2)$ normalized at ∞ and set $\tilde{m} = m\delta^{-\sigma_3}$, $\sigma_3 = \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix}$. Then $\tilde{m}$ solves the normalized RHP $(\mathbb{R}, \tilde{v}_\theta)$, where $\tilde{v}_\theta$ is as in Figure 2.

$$\begin{pmatrix} 1 & 0 \\ -\bar{r}\delta_-^{-2}(1 - |r|^2)^{-1}e^{-i\theta} & 1 \end{pmatrix} \begin{pmatrix} 1 & r\delta_+^{-2}(1 - |r|^2)^{-1}e^{i\theta} \\ 0 & 1 \end{pmatrix} \quad \bullet \quad \begin{pmatrix} 1 & r\delta^2 e^{i\theta} \\ 0 & 1 \end{pmatrix} \begin{pmatrix} 1 & 0 \\ -\bar{r}\delta^{-2}e^{-i\theta} & 1 \end{pmatrix}$$

z_0

Figure 2. The jump matrix $\tilde{v}_\theta$.

Assuming (as we may, after suitable approximation) that the entries of $\tilde{v}_\theta$ have analytic extensions, define m_θ^d as in Figure 3. Note that, with this definition, m_θ^d solves the normalized RHP $(\Sigma_{z_0}^d, v_\theta^d)$, where v_θ^d is shown in Figure 4.

Figure 3. The solution m_θ^d .

Figure 4. The jump matrix v_θ^d .

Observe that the definition of δ and the choice of the lower/upper and upper/lower factorizations of $\tilde{v}_\theta$, were made precisely to take advantage of the signature table of $\text{Re } i\theta = -t \text{Re } i(z - z_0)^2$ in Figure 5.

As $t \rightarrow \infty$, $v_\theta^d \rightarrow I$ uniformly on $\Sigma_{z_0}^d \setminus \{|z - z_0| \geq \varepsilon\}$ for any $\varepsilon > 0$, and the RHP localizes at z_0 to an RHP that can be solved explicitly. We obtain as $t \rightarrow \infty$

$$q(x, t) = t^{-1/2} \alpha(z_0) e^{i[x^2/(4t) - v(z_0) \log 2t]} + O(\log t/t), \tag{11}$$

where

$$v(z) = -\frac{1}{2\pi} \log(1 - |r(z)|^2), \quad |\alpha(z)|^2 = v(z)/2 \tag{12}$$

and

$$\arg \alpha(z) = \frac{1}{\pi} \int_{-\infty}^z \log(z - s) d \log(1 - |r(s)|^2) + \frac{\pi}{4} + \arg \Gamma(iv(z)) + \arg r(z). \tag{13}$$

The above asymptotic form was first obtained by Zakharov and Manakov but without the error estimate. The RHP/steepest-descent method, suitably extended,

Figure 5. Signature of $\text{Re } i\theta$.

has also been used by Deift and Zhou to obtain precise long-time asymptotics of solutions of perturbed NLS equations.

In the above problem, the leading order asymptotic contribution arises from the stationary phase point, as in the classical method of stationary phase for scalar integrals. In many problems, in fact in most problems, the leading order contribution no longer arises from one (or more) critical points, but is given instead by a “critical contour.” Such a contour arises, for example, in the asymptotic analysis as $x \rightarrow \infty$ of the Painlevé equation by Deift and Zhou, and also in the analysis of the collisionless shock region by Deift, Venakides and Zhou. In Deift, Venakides and Zhou (1997), in the context of the zero-dispersion limit of the Kortweg–de Vries (KdV) equation, the method in Deift & Zhou (1993) was extended significantly to include a prescription for the determination of the critical contour, making it possible in turn to describe the asymptotic development of fully nonlinear oscillations. This extension of Deift & Zhou (1993) made it possible to obtain Plancherel–Rotach-type asymptotics for a general class of orthogonal polynomials, leading in turn to a solution of the so-called universality conjecture for unitary ensembles (see Deift et al., 1999, and **Random Matrix Theory IV: Analytic methods**; see also the work of Pastur and Scherbina for a different approach, and also the work of Bleher and Its for an approach related to Deift et al. (1999), in the special case of a quartic potential). Many other long-standing problems in mathematics and in physics have been solved since the 1990s using RHP techniques and the (extended) steepest-descent method. For example, in combinatorics, Ulam’s problem for increasing subsequences in random permutations was solved completely by Baik, Deift, and Johansson in terms of the Tracy–Widom distribution of random matrix theory, giving rise in turn to an explosive growth in applications linking combinatorics, statistical models, and random matrix theory. Many people are contributing to these developments, but there is as yet no adequate review. Fortunately, a comprehensive review, by T. Kriecherbauer, is due to appear in *Nonlinearity* in early 2005. Further extensions of the RHP/steepest-descent method have been given recently in the work of Kamvissis, McLaughlin and Miller on the semiclassical limit for the defocusing nonlinear Schrödinger equation.

Finally, we return to the classical Faddeev–Marchenko approach to inverse scattering theory mentioned earlier and make some comparisons with the RHP method. First, as noted above, the Faddeev–Marchenko equation arises by taking a Fourier transform of objects arising in the RHP theory. This means, in particular, that the classical method only applies in cases where the underlying contour is a group such as a line or a circle; problems such as Painlevé II, for example, cannot be handled in general by the classical method. Second, even in cases where the underlying contour is a group, such as NLS or KdV, the leading order contribution to the solution as $t \rightarrow \infty$ arises from the stationary phase points. Taking a Fourier transform “smears out” this feature and the microlocal nature of the problem is obscured.

Beals & Coifman (1984) were the first to use RHPs for the rigorous analysis of scattering and inverse scattering theory.

RÖSSLER SYSTEMS

Rössler systems were introduced in the 1970s as prototype equations with the minimum ingredients for continuous-time chaos.

Since the Poincaré–Bendixson theorem precludes the existence of other than steady, periodic, or quasi-periodic attractors in autonomous systems defined in one- or two-dimensional manifolds such as the line, the circle, the plane, the sphere, or the torus (Hartman, 1964), the minimum dimension for chaos is three. On this basis, Otto Rössler came up with a series of prototype systems of ordinary differential equations in three-dimensional phase spaces (Rössler, 1976a,c, 1977a, 1979a). He also proposed four-dimensional systems for hyperchaos, that is, chaos with more than one positive Lyapunov exponent (Rössler, 1979a,b).

Figure 1. Illustration of the reinjection principle between the two branches of a Z-shaped slow manifold allowing (a) periodic relaxation oscillations in dimension two and (b) higher types of relaxation behavior in dimension three.

Rössler was inspired by the geometry of flows in dimension three and, in particular, by the reinjection principle, which is based on the feature of relaxation-type systems to often present a Z-shaped slow manifold in their phase space. On this manifold, the motion is slow until an edge is reached whereupon the trajectory jumps to the other branch of the manifold, allowing not only for periodic relaxation oscillations in dimension two (see Figure 1a), but also for higher types of relaxation behavior (see Figure 1b) as noted by Rössler (1979a). In dimension three, the reinjection can induce chaotic behavior if the motion is spiraling out on one branch of the slow manifold (see Figure 1b). In this way, Rössler invented a series of systems, the most famous of which is probably (Rössler 1979a):

$$\begin{aligned}\frac{dx}{dt} &= -y - z, \\ \frac{dy}{dt} &= x + ay, \\ \frac{dz}{dt} &= bx - cz + xz.\end{aligned}\tag{1}$$

This system is minimal for continuous chaos for at least three reasons: its phase space has the minimal dimension three, its nonlinearity is minimal because there is a single quadratic term, and it generates a chaotic attractor with a single lobe, in contrast to the Lorenz attractor which has two lobes. In Equation (1), (x, y, z) are the three variables that evolve in the continuous time t , and (a, b, c) are three parameters. The linear terms of the two first equations create oscillations in the variables x and y . These oscillations can be amplified if $a > 0$, which results into a spiraling-out motion. The motion in x and y is then coupled to the z variable ruled by the third equation, which contains the nonlinear term and which induces the reinjection back to the beginning of the spiraling-out motion.

System (1) possesses two steady states: one at the origin $x = y = z = 0$, around which the motion spirals out, and another one at some distance from the origin due to the quadratic nonlinearity. This system presents stationary, periodic, quasi-periodic, and chaotic attractors depending on the

Figure 2. Phase portraits of the Rössler system (1) in the phase space of the variables (x, y, z) : (a) spiral-type chaos for $a = 0.32$, $b = 0.3$, and $c = 4.5$; (b) screw-type chaos for $a = 0.38$, $b = 0.3$, and $c = 4.820$, in which case there also exists the Shil'nikov-type homoclinic orbit (c). The ticks are separated by unity. (Adapted from Gaspard & Nicolis, 1983.)

value of the parameters (a, b, c) . These attractors are interconnected by bifurcations, in particular, a Hopf bifurcation from the stationary to periodic attractors and a period-doubling cascade from periodic to chaotic attractors. The resulting chaotic attractor has a single lobe and is referred to as spiral-type chaos, which mainly manifests itself in irregular amplitudes for the oscillations (see Figure 2a).

A transition occurs to a screw-type chaos in which the oscillations are irregular not only in their amplitudes but also in the reinjection times (see Figure 2b). The

screw-type chaos is closely related to the presence of a Shil'nikov homoclinic orbit (see Figure 2c). This homoclinic orbit is attached to the origin $x = y = z = 0$, which is a saddle-focus with a one-dimensional stable manifold for the reinjection and a two-dimensional unstable manifold where the motion is spiraling out. The Shil'nikov criterion for chaos is that the reinjection is faster than the spiraling-out motion (Shil'nikov, 1965), and it is satisfied in the attractor of Figure 2b. As a consequence, the homoclinic system contains periodic and nonperiodic orbits belonging to multiple horseshoes that can be described in terms of symbolic dynamics. Away from homoclinicity, the system undergoes complex bifurcation cascades generating successive periodic and chaotic attractors.

Chaotic behavior and Shil'nikov homoclinic orbits in the Rössler system (1) can also be understood as originating from an oscillatory-stationary double instability taking place around the origin $x = y = z = 0$ and the parameter values $b = 1$, $-\sqrt{2} < a = c < \sqrt{2}$.

In his work on continuous chaos, Rössler was motivated by the search for chemical chaos, that is, chaotic behavior in far-from-equilibrium chemical kinetics (Ruelle, 1973; Rössler, 1976b, 1977b; Rössler & Wegmann, 1978). With Willamowski, Rössler proposed the following chemical reaction scheme:

which features two autocatalytic steps (reactions 1 and 5) involving the species X and Z coupled to another autocatalytic step (reaction 2) involving another species Y and two further steps (reactions 3 and 4) (Willamowski & Rössler, 1980). The concentrations of the species $A_1, \dots, A_5$ are held fixed by large chemical reservoirs that maintain the system out of thermodynamic equilibrium. The time evolution of the concentrations (x, y, z) of the three intermediate species X, Y , and Z is ruled by a system of three coupled differential equations deriving from the mass action law of chemical kinetics. These equations have quadratic nonlinear terms because of the binary reactive steps and keep the concentrations positive as a consequence of mass action kinetics. The chemical reaction scheme (2) leads to a chaotic attractor very similar to that of the abstract system (1) (see Figure 3), and thus provides a

Chaotic time evolution of the concentrations of the Willamowski-Rössler chemical reaction scheme (2) for $k_1a_1 = 30$, $k_{-1} = 0.5$, $k_2 = 1$, $k_{-2} = 0$, $k_3a_5 = 10$, $k_{-3} = 0$, $k_4 = 1$, $k_{-4} = 0$, $k_5a_4 = 16.5$, and $k_{-5} = 0.5$: (a) phase portrait in the plane of the concentrations of species X and Y ; (b) concentration of species X versus time t .

mechanistic understanding of chemical chaos in terms of colliding and reacting particles.

In conclusion, Rössler systems are minimal models for continuous-time chaos. The chaotic attractors of Rössler systems are prototypes for a large variety of chaotic behavior, notably, in chemical chaos (Scott, 1991).

ROTATING RIGID BODIES

Rigid body motion about a fixed point is a classical mechanics problem associated with the greatest names in 18th-century mathematics. The basic equations of the motion were derived by Leonhard Euler in the 1750s and subsequently solved by him for two special cases (Euler and Lagrange tops). Development of the analytical theory of differential equations in the middle of the 19th century by Augustin Cauchy, Georg Riemann, and Karl Weierstrass inspired Sophia Kovalevsky (1889) to determine all the cases for which the integrals of rigid body dynamics were *single-valued, meromorphic* functions in the entire *complex* plane of the time variable. Pursuing this remarkable idea, she obtained a classification of all such (solvable) cases and found a new case, the Kovalevsky top, which she then integrated in quadratures. Considering time as a complex variable and imposing the above conditions upon the integrals of the equations of motion outside the real axis was a revolutionary approach to treating a mechanics problem. It appeared to be a fruitful method that led to a unified theory of (algebraically) completely integrable systems (Adler & van Moerbeke, 1989), a century after it was proposed.

The dynamics of a rigid body rotating about a fixed point can be considered in a fixed (nonmoving) frame of axes or in the moving body frame that has its origin at the fixed point and whose axes are along the principal axes of the ellipsoid of inertia. In 1750, Euler obtained the equations of motion in a fixed frame, but they appeared not to be very useful. In a series of papers during 1758–1765, he introduced the body frame, derived corresponding equations of motion, and also used Eulerian angles to relate the motion of a body frame with respect to a fixed system of coordinates.

Consider first a fixed frame (i', j', k'). A fundamental dynamical theorem says that the time derivative of the angular momentum $\mathbf{J}$ of a body is equal to the moment $\mathbf{L}$ of the forces acting on it,

$$\frac{d\mathbf{J}}{dt} = \mathbf{L}. \quad (1)$$

In the body frame, (i, j, k), the tensor of inertia is diagonal, $\mathbf{I} = \text{diag}(A, B, C)$, and links the vector of angular velocity $\boldsymbol{\Omega} = p\mathbf{i} + q\mathbf{j} + r\mathbf{k}$ to the angular momentum $\mathbf{J}$ through the linear relation

$$\mathbf{J} = \mathbf{I}\boldsymbol{\Omega} = Ap\mathbf{i} + Bq\mathbf{j} + Cr\mathbf{k}. \quad (2)$$

The time derivative of vector (2) is

$$\frac{d\mathbf{J}}{dt} = \frac{\delta\mathbf{J}}{\delta t} + \boldsymbol{\Omega} \times \mathbf{J}, \quad (3)$$

where $\frac{\delta\mathbf{J}}{\delta t}$ is the relative time derivative, evaluated assuming that the frame (i, j, k) is stationary. The first three Euler equations, therefore, are

$$\begin{aligned} A \frac{dp}{dt} + (C - B)qr &= Mg(y_0\gamma'' - z_0\gamma'), \\ B \frac{dq}{dt} + (A - C)rp &= Mg(z_0\gamma' - x_0\gamma''), \\ C \frac{dr}{dt} + (B - A)pq &= Mg(x_0\gamma' - y_0\gamma''), \end{aligned} \quad (4)$$

where $M\mathbf{g} = Mg(\gamma\mathbf{i} + \gamma'\mathbf{j} + \gamma''\mathbf{k})$ is the vector of the gravitational force and $\mathbf{r}_0 = x_0\mathbf{i} + y_0\mathbf{j} + z_0\mathbf{k}$ is the vector originating in the fixed point and pointing at the center of mass of the body. An extra set of three equations follows from the fact that the vector $M\mathbf{g}$ is stationary in the fixed frame; hence, $\frac{\delta M\mathbf{g}}{\delta t} = -\boldsymbol{\Omega} \times M\mathbf{g}$ and

$$\begin{aligned} \frac{d\gamma}{dt} &= r\gamma' - q\gamma'', & \frac{d\gamma'}{dt} &= p\gamma'' - r\gamma, \\ \frac{d\gamma''}{dt} &= q\gamma - p\gamma'. \end{aligned} \quad (5)$$

The Eulerian angles, namely, the angle of precession $0 \leq \psi < 2\pi$, the angle of nutation $0 \leq \vartheta \leq \pi$, and the angle of the self rotation $0 \leq \varphi < 2\pi$, define the body's position by fixing the moving frame with respect to the fixed one. We have (see Golubev, 1960)

$$\begin{aligned} \gamma &= \sin \varphi \sin \vartheta, & \gamma' &= \cos \varphi \sin \vartheta, \\ \gamma'' &= \cos \vartheta, \end{aligned} \quad (6)$$

$$\begin{aligned} p &= \dot{\psi} \sin \vartheta \sin \varphi + \dot{\vartheta} \cos \varphi, \\ q &= \dot{\psi} \sin \vartheta \cos \varphi - \dot{\vartheta} \sin \varphi, & r &= \dot{\psi} \cos \vartheta + \dot{\varphi} \end{aligned} \quad (7)$$

and, therefore,

$$\frac{d\psi}{dt} = \frac{p\gamma + q\gamma'}{\gamma^2 + \gamma'^2}. \quad (8)$$

The problem of studying the motion of a rigid body about a fixed point is solved by integration of the system of differential equations (4), (5), and (8).

Conserved Quantities

It is always useful to know a system's first integrals, for instance for controlling numerical calculations or for performing integration in quadratures. There are three important physical integrals for an arbitrary top (an arbitrary set of the six parameters $\{A, B, C, x_0, y_0, z_0\}$ in Equations (4)). They are the following.

- (i) Energy integral: $E = \frac{1}{2} (Ap^2 + Bq^2 + Cr^2) - Mg(x_0\gamma + y_0\gamma' + z_0\gamma'')$.
- (ii) Length of the unit vector along Mg : $C_1 = \gamma^2 + \gamma'^2 + \gamma''^2 = 1$.
- (iii) Projection of the angular momentum $\mathbf{J}$ on this vector: $C_2 = Ap\gamma + Bq\gamma' + Cr\gamma''$.

These three first integrals provide three constants of motion (since $C_1 = 1$, there are, in fact, only two arbitrary constants, the third one being the integration constant that appears when integrating (8), that is, the initial value of ψ). In addition, an autonomous system always has an extra constant corresponding to shifting of the time variable t . A remarkable feature of Equations (4) and (5) is that yet another explicit integration can be carried out using the method of Jacobi's last multiplier (Golubev, 1960), bringing in another explicit constant of integration. Therefore, for the case of a complete integration in quadratures of the equations of motion only one first integral is missing. Subsequent analysis showed that an extra algebraic integral exists only in the three special cases of Euler, Lagrange, and Kovalevsky tops. These integrable tops are given by specializing the parameters $\{A, B, C, x_0, y_0, z_0\}$.

Integrable Tops

The simpler cases of the Euler and Lagrange tops were studied, respectively, by Euler and Louis Poinsot and by Joseph-Louis Lagrange and Siméon Poisson, and later on by Gustav Jacobi, who expressed the general integrals for both systems in terms of elliptic functions of time.

Euler Top

In the Euler top $x_0 = y_0 = z_0 = 0$, and the body's center of mass is at the fixed point, so that there is no gravitational effect, meaning a free rotation of an asymmetric top. The fourth integral of motion in this case is the square of the angular momentum $\mathbf{J}$:

$$J^2 = A^2 p^2 + B^2 q^2 + C^2 r^2. \quad (9)$$

Poinsot gave a geometric interpretation of the motion based on the intersection of two quadratics: (9) and the energy integral $2E = Ap^2 + Bq^2 + Cr^2$. The vector $\mathbf{J}$ is stationary in the fixed frame $(\hat{i}', \hat{j}', \hat{k}')$ and the problem is made simpler if one chooses $\hat{k}'$ along $\mathbf{J}$.

Then

$$\cos \vartheta = \frac{Cr}{|\mathbf{J}|} \text{ and } \tan \varphi = \frac{Ap}{Bq}. \quad (10)$$

As for time dependence, the variables p, q , and r can be expressed in terms of Jacobi's elliptic functions sn, cn , and dn of time and they are periodic, so are ϑ and φ obtained from (10). The dynamics of the angle of precession ψ is determined by integration of $\dot{\psi} = |\mathbf{J}| \frac{Ap^2 + Bq^2}{A^2 p^2 + B^2 q^2} > 0$, derived from (8). It follows that after each period, the value of ψ , in general, changes, so that the body never comes back to its initial orientation, thereby undergoing quasi-periodic motion.

Stationary rotations are those when the vector of angular velocity $\boldsymbol{\Omega}$ is constant. They correspond to uniform rotations about the principal axes of inertia. Rotation around the middle axis is unstable.

A symmetric ($A = B$) Euler top performs regular precession. The body's symmetry axis draws a circular conic with the axis $\mathbf{J}$ and the angle $2\vartheta = \text{const}$. The symmetry axis goes around $\mathbf{J}$ with a constant angular velocity while the body rotates with a constant angular velocity around the symmetry axis.

Lagrange Top

This describes the dynamics of a symmetric body, $A = B$, with the fixed point at the symmetry axis and off the center of mass, that is, $x_0 = y_0 = 0, z_0 \neq 0$. The fourth constant of motion is simply r . The integration of this top can again be done in terms of elliptic functions, leading to a variety of complicated quasi-periodic motions including pseudo-regular precession, double-asymptotic, and "sleeping" tops. Simpler motions correspond to degenerations of elliptic functions into elementary functions.

The motion of the symmetry axis, described by the angles ϑ and ψ , looks like a perturbation of the corresponding uniform rotation of a symmetric Euler top in the regular precession. Illustrations of this familiar motion are available in many textbooks. Notice that now $\dot{\psi}$ can change sign, thereby giving three kinds of trajectories.

Denote $m = 1 - C/A$ and notice that $m = 0$ for a spherically symmetric body ($A = B = C$). Consider the Lagrange top with $m \neq 0$ and the variables $(p, q, r, \gamma, \gamma', \gamma'')$ and a fully symmetric Lagrange top with $m = 0$ and the variables $(p_1, q_1, r_1, \gamma_1, \gamma_1', \gamma_1'')$. It is possible to show that the motions of these two bodies coincide when the variables are identified as follows:

$$\begin{aligned} p_1^2 + q_1^2 &= p^2 + q^2, & \tan^{-1} \frac{q_1}{p_1} &= \tan^{-1} \frac{q}{p} + mrt, \\ r_1 &= \frac{C}{A} r, & & \\ \varphi_1 &= \varphi - mrt, & \vartheta_1 &= \vartheta, \\ \psi_1 &= \psi. \end{aligned} \quad (11)$$

See Golubev (1960) for details.

Kovalevsky Top

This is the third general case of complete integrability of the Euler equations (4) and (5), which is characterized by restricting $A = B = 2C$ and $y_0 = z_0 = 0$. Hence, the Kovalevsky top is a special symmetric top whose center of mass lies in the equatorial plane of the ellipsoid of inertia ($x_0 \neq 0$). The fourth constant of motion is of order 4:

$$K = \left(p^2 - q^2 + \frac{Mgx_0}{C} \gamma \right)^2 + \left(2pq + \frac{Mgx_0}{C} \gamma' \right)^2. \quad (12)$$

Kovalevsky found this case (Kovalevsky, 1889) and integrated it in terms of hyper-elliptic functions. Later on, Kötter (1893) simplified the formulae.

There is a great difference in complexity between this top and the other two. This is why there was such a long period between the discovery and integration of Euler and Lagrange tops and that of Kovalevsky. The Paris Academy of Sciences established a special Borden Prize to promote major expansions of the theory. It was finally claimed in 1888 by Sophia Kovalevsky who made major progress toward solution of the problem. Her work required usage of theta-functions in two variables and provided an enormous boost to the creation of the modern theory of completely integrable systems. There is a large body of literature about the Kovalevsky top, of which we mention only three items. In Adler & van Moerbeke (1988), a detailed study of the algebraic geometry of the model is given. In Bobenko et al. (1989), the authors find alternative theta-function formulae by making use of the corresponding Lax matrix and the finite-gap integration technique. In Kuznetsov (2002), connections with a representation of the quadratic r -matrix algebra and with the method of separation of variables are presented.

All other general tops corresponding to other choices of the six parameters (A, B, C, x_0, y_0, z_0) are not integrable, which means that they generally exhibit a chaotic dynamics, and it is impossible to find analytic solutions valid for arbitrary initial conditions.

ROTATING WAVE APPROXIMATION

Energy conserving oscillators comprise pairs of energetic variables (let us call them P and Q), each being the cause of the other. In a mechanical (spring-mass) oscillator shown in Figure 1, for example, Q would be the displacement of a mass and P its momentum (mass times velocity). For a radio engineer's tank oscillator, Q is the voltage across a capacitor and P is the current through an inductor. In a laser mode, Q is electric field energy and P is magnetic field energy.

Consider the mechanical oscillator of Figure 1, assuming the spring to be linear. From Newton's second law (force equals time derivative of momentum), the dynamic equation describing this system is

$$\frac{d}{dt} \left(M \frac{dx}{dt} \right) = -Kx, \quad (1)$$

where x is the vertical displacement of the mass from its resting position and M is the oscillator mass. On the right-hand side of this equation is the vertical force acting on the mass caused by extension or compression of the spring, and on the left-hand side is the time derivative of the vertical momentum: $p \equiv Mdx/dt$. In this case, a solution is evidently $x = a \sin(\omega_0 t)$, where a is an arbitrary amplitude and $\omega_0 = \sqrt{K/M}$ is the frequency of oscillation.

Often the force of a spring is not quite a linear function of its extension but slightly sublinear. (This

Figure 1. A spring-mass oscillator.

is the case, for example, in molecular vibrations, where the force between a pair of atoms becomes relatively weaker as the distance between them is increased because the electronic contribution to interatomic bonding is lessened.) In such cases, it is convenient to introduce anharmonicity into the formulation through the rotating wave picture (Louisell, 1960; Scott, 2003).

In the rotating wave picture of a linear oscillator, the momentum (p) and extension (x) are combined as real and imaginary parts of a single, complex amplitude

$$A \equiv \frac{(p - iM\omega_0 x)}{\sqrt{2M\omega_0}}, \quad (2)$$

which obeys the first order equation

$$i \frac{dA}{dt} = \omega_0 A \quad (3)$$

with the solution $A(t) = A(0)e^{-i\omega_0 t}$. Under this formulation, the total energy of the oscillator is

$$H = \omega_0 |A|^2 = \frac{1}{2} \left(\frac{p^2}{M} + Kx^2 \right), \quad (4)$$

where the first term is the kinetic energy of the moving mass and the second is the potential energy stored in the spring.

If the restoring force of the spring is slightly sublinear, its potential energy may depend upon x as

$$\text{potential energy} = \frac{1}{2} Kx^2 - \frac{1}{4} \alpha x^4, \quad (5)$$

where $\alpha > 0$ is an anharmonicity parameter. With $\alpha = 0$, $x = i(A - A^*)/\sqrt{2M\omega_0}$, so

$$x^4 = \frac{1}{4M^2\omega_0^2} [A^4 - 4A^3A^* + 6|A|^4 - 4A(A^*)^3 + (A^*)^4]. \quad (6)$$

Except for the middle $6|A|^4$ term, each term in Equation (6) varies sinusoidally with time at frequencies $\pm 4\omega_0$ or $\pm 2\omega_0$. Thus, the average of the energy over a cycle of oscillation is

$$\langle H \rangle = \omega_0 |A|^2 - \frac{\gamma}{2} |A|^4, \quad (7)$$

where $\gamma = 3\alpha/4M^2\omega_0^2$.

Under the rotating wave approximation (RWA), the energy H is taken as equal to its time average $\langle H \rangle$, whereupon the complex amplitude A is governed by the first order ODE

$$i \frac{dA}{dt} \doteq \omega_0 A - \gamma |A|^2 A. \quad (8)$$

In this expression, the symbol “ $\doteq$ ” indicates that only terms of frequency ω_0 are included. In other words, all nonresonant terms are neglected in the RWA.

Since Equation (8) conserves $N = |A|^2$, a general solution of this equation is

$$A(t) = \sqrt{N} e^{-i[(\omega_0 - \gamma N)t + \varphi]}, \quad (9)$$

where φ is an arbitrary phase angle. Equation (9) gives the frequency ($\omega = \omega_0 - \gamma N$) of the nonlinear oscillation as a function of its amplitude in the RWA.

Thus, RWA accounts for all components generated by a weak nonlinearity that resonate with the fundamental oscillator frequency. (As with your radio receiver, those components not in resonance are neglected.) Because the RWA is motivated by a general oscillator formulation, it is widely employed as the initial assumption in a variety of nonlinear analyses (various versions of the nonlinear Schrödinger equation, the discrete self-trapping equation, molecular vibrations, nonlinear optics, etc.). Interestingly, odd terms in the potential function (x^3 , x^5 , and so on) do not generate resonant components and are, thus, neglected in the RWA.

Finally, the RWA is a convenient formulation because quantum theories are easy to construct and solve for general systems of interacting oscillators, including discrete nonlinear Schrödinger equations and the discrete self-trapping system (Louisell, 1962; Scott et al., 1994; Scott, 2003). This is so for two reasons. First, under quantum theory in the RWA, the complex amplitude (A) becomes the lowering (annihilation) operator for oscillator quanta (bosons), and its complex conjugate (A^*) becomes the raising (creation) operator. Second, the classical fact that $N = \sum |A|^2$ is conserved implies that the corresponding quantum number operator commutes with the energy operator, allowing eigenfunctions of the energy operator to be constructed as sums of linear oscillator eigenfunctions.

ROUTES TO CHAOS

If a nonlinear systems has chaotic dynamics, then it is natural to ask how this complexity develops as

parameters vary. For example, in the logistic map

$$x_{n+1} = rx_n(1 - x_n), \tag{1}$$

it is easy to show that if $r = \frac{1}{2}$, then there is a fixed point at $x = 0$ that attracts all solutions with initial values x_0 between 0 and 1, while if $r = 4$, the system is chaotic. How, then, does the transition to chaos occur as the parameter r varies? Indeed, is there a clean transition to chaos in any well-defined sense? The identification and description of routes to chaos has had important consequences for the interpretation of experimental and numerical observations of nonlinear systems. If an experimental system appears chaotic, it can be very difficult to determine whether the experimental data comes from a truly chaotic system, or if the results of the experiment are unreliable because there is too much external noise. Chaotic time series analysis provides one approach to this problem, but an understanding of routes to chaos provides another. In many experiments there are parameters (ambient temperature, Raleigh number, etc.) that are fixed in any realization of the experiment, but which can be changed. If recognizable routes to chaos are observed when the experiment is repeated at different values of the parameter, then there is a sense in which the presence of chaotic motion has been explained.

By the early 1980s, three “scenarios” or “routes to chaos” had been identified (e.g., Eckmann, 1981): Ruelle–Takens–Newhouse, period doubling, and intermittency (which has several variants). As we shall see, in their standard forms each of these transitions uses the term “route to chaos” in a different way, so care needs to be taken over the interpretation of experimental or numerical observations of these transitions.

Ruelle–Takens–Newhouse

In 1971, Ruelle and Takens published a mathematical paper with the provocative title “On the Nature of Turbulence.” In this paper and a subsequent improvement with Newhouse (1978), they discuss the Landau scenario for the creation of turbulence by the successive addition of new frequencies to the dynamics of the fluid. They show that if the attractor of a system has three independent frequencies (four in the 1971 paper), then a small perturbation of this system has a hyperbolic strange attractor—a Plykin attractor (a solenoid in the 1971 paper). The result became known colloquially as “three frequencies implies chaos,” a serious misinterpretation of the mathematical result that has been the cause of a number of misleading statements. First, the result proves the existence of chaos in systems arbitrarily close to the three frequency system in an infinite dimensional function space but gives no indication of the probability of finding chaos in any given example. Second, I know of no experimental situation where a Plykin attractor has

Figure 1. The attractor of the logistic equation as a function of the parameter r .

been shown to exist even when chaotic behavior has been observed close to systems with three frequency attractors. Numerical experiments suggest that it is much more likely that the system evolves by frequency locking. The Ruelle–Takens–Newhouse route to chaos remains somewhat of an enigma, and more work needs to be done to understand precisely how and when the strange attractors predicted by the theory come into being.

Period Doubling

Figure 1 shows the attractor of the logistic map (1) as a function of the parameter, r , for $3.5 < r < 4$. Thus, the set of points plotted on any vertical line of constant r represents the attractor of the map for that value of r , and if the set is finite, then the (numerically computed) attractor is a periodic orbit that cycles through the finite collection of points. Figure 1 suggests that for small r , the attractor is always periodic and has period 2^n , with n increasing as r increases. Beyond some critical value $r = r_c$, with $r_c \approx 3.569946$, the attractor may be more complicated. There are clearly intervals of r for which the attractor is periodic, and the attractor seems to be contained in 2^n bands that merge as r increases (the final band merging from 2 bands to one band with r just below 3.68 is particularly clear).

As r increases, the periodic orbit of period 2^n is created from the orbit of period 2^{n-1} by a period-doubling bifurcation. If this bifurcation occurs with $r = r_n$, then $r_n \rightarrow r_c$ geometrically as $n \rightarrow \infty$, with

$$\lim_{n \rightarrow \infty} \frac{r_n - r_{n-1}}{r_{n+1} - r_n} = \delta \approx 4.66920, \tag{2}$$

i.e., $r_n \rightarrow r_c - \kappa \delta^{-n}$.

The really surprising feature of this period-doubling cascade, as shown in Feigenbaum (1978), is that the cascade can be observed in many maps and the accumulation rate δ of the period-doubling cascade (2)

Figure 2. (a) The quadratic map $f(x) = 1 - mx^2$ restricted to the interval $[-1, 1]$ and the second iterate, $f(f(x))$ for $m = 1.40115$ which is just below the critical value m_c . (b) The original map, f , and the rescaled map, $F_2(x) = \mathcal{T}f(x) = -a^{-1}f(f(-ax))$ on $[-1, 1]$ with $a = -f(1) = m - 1$. Note that $a = 0.40115$ is close to the universal value of $\alpha \approx 0.3995$.

is the same although the constants r_c and κ depend on the map. In fact, the universal value of δ depends on the nature of the maximum of the map: $\delta \approx 4.66920$ for maps with quadratic maximum. A complete cascade of band merging from 2^n bands to 2^{n-1} bands occurs at parameter values r_n above r_c , and $r_n \rightarrow r_c$ as $n \rightarrow \infty$ at the same universal geometric rate δ .

The quantitative universality in parameter space described by the scaling δ has a counterpart in phase space. If x_n denotes the point on the periodic orbit of period 2^{n-1} that is closest to the critical point (or turning point) of the map with $r = r_n$, then

$$\lim_{n \rightarrow \infty} \frac{x_{n+1} - \frac{1}{2}}{x_n - \frac{1}{2}} = -\alpha, \quad (3)$$

where α is another universal constant, which, for maps with a quadratic turning point, takes the value $\alpha \approx 0.3995 = 1/2.50 \dots$

In families of one hump (unimodal) maps this universality can be explained by a renormalization argument. Restrict attention to families of one hump maps with critical point (maximum) at $x = 0$, parametrized by μ and normalized so that $f(0)c = 1$. As shown in Figure 2a, for parameter values near μ_c (the accumulation of period doubling) the second iterate of the map, $f(f(x))$, restricted to an interval about the critical point is a one hump map with a minimum. So, after a rescaling (and flipping) of the coordinates, it is another one hump map with the same normalization as shown in Figure 2b. Mitchell Feigenbaum was able to show (by arguments that have been made rigorous since 1990) that the universal properties described above are due to the structure of the doubling operator $\mathcal{T}$, which is a map on one hump maps $f: [-1, 1] \rightarrow [-1, 1]$, with critical point at $x = 0$ and $f(0)c = 1$, defined by

$$\mathcal{T}f(x) = -a^{-1}f(f(-ax)), \quad (4)$$

where $a = -f(1)$ so that the normalization $\mathcal{T}f(0) = 1$ is preserved. This operator does the rescaling and flipping referred to above. In the appropriate universal-

ity class, for example, quadratic critical point together with some further technical conditions, there is a fixed point f_* , of $\mathcal{T}$, so $f_* = \mathcal{T}f_*$, and the universal scaling of phase space is given by $\alpha = -f_*(1)$. Furthermore, the universal accumulation rate δ of (2) is an unstable eigenvalue of the (functional) derivative of $\mathcal{T}$ at f_* .

We can now consider measures of chaos such as the topological entropy or the Lyapunov exponents of the map. If $\{f_\mu\}$ is a family of one hump maps that undergoes period doubling, then the parameter μ can be chosen so that the period-doubling cascade is for $\mu < \mu_c$. Coullet & Tresser (1980) show that the universal structure described above implies that if $H(\mu)$ is either the topological entropy (which can be thought of as the growth rate of the number of periodic orbits) or the Lyapunov exponent of f_μ with $\mu > \mu_c$, then

$$H(\mu) \sim C(\mu - \mu_c)^{(\log 2)/(\log \delta)}. \quad (5)$$

The Lyapunov exponent is a very poorly behaved function of the parameters and this scaling provides only an envelope for the graph of the exponent, but the topological entropy is continuous. Indeed, the proof of Sharkovsky's theorem (See **One-dimensional maps**) shows that if a continuous map of the interval has a periodic orbit which is not a power of two, then there is a horseshoe for some iterate of the map, and hence the map has positive topological entropy if $\mu > \mu_c$. The entropy is zero if $\mu < \mu_c$, so if by chaos we mean positive topological entropy, then the period-doubling route is a true route to chaos.

Intermittency

The first stable periodic orbit of each of the windows of periodic motion in $r > r_c$, which can be seen in Figure 1, is created in a saddle-node (or tangent) bifurcation. Throughout the parameter interval for which such orbits are stable, there is a repelling strange invariant set, but most solutions tend to the stable periodic orbit. Just before the creation of the stable periodic orbit, chaotic solutions spend long periods of time near the points at which the stable periodic orbit will be created (the "laminar" phase), then move away and behave erratically before returning to the laminar phase. This behavior is called intermittency by Pomeau & Manneville (1980), who were the first to describe the scaling of the time spent in the laminar phase. They looked at the average time T_A spent by solutions in the laminar phase as a function of the parameter r close to the value r_{sn} , at which the saddle-node bifurcation occurs. A simple argument based on the passage time of a trajectory of a map close to a tangency with the diagonal (the condition for the saddle-node bifurcation) establishes that the average time in the laminar phase diverges as a power law:

$$T_A \sim |r - r_{sn}|^{-1/2}. \quad (6)$$

Other types of intermittency (involving period-doubling bifurcations, etc.) can be analyzed using the same ideas. Note that a strange invariant set exists throughout the parameter regions being considered here, so in this case the term “route to chaos” refers to the stability of the chaotic invariant set, not the creation of a chaotic set. Moreover, in any open neighborhood of r_{sn} , there are parameters for which the map has other stable periodic orbits, so the full description of parameters with stable chaotic motion is much more complicated than the description above suggests.

Other Routes to Chaos

Since the pioneering work of the late 1970s, a number of other routes to chaos have been identified. New routes to chaos are still being identified, and the list provided here is by no means complete. Arnéodo et al. (1981) show that there can be cascades of homoclinic bifurcations to chaos via a mechanism closely related to period doubling. This gives the less standard convergence rates involving nonquadratic turning points immediate relevance. The bifurcation that creates the strange invariant set of the Lorenz model is another type of homoclinic bifurcation, and this strange invariant set becomes stable by a “crisis” in which the strange invariant set collides with a pair of unstable periodic orbits. Ott (2002) contains a good account of such transitions. More complicated transitions involving maps of the circle are detailed in MacKay & Tresser (1986), and Newhouse et al. (1983) give another transition.

SALERNO EQUATION

The Salerno equation is a q -deformed lattice model that includes, as particular cases, two known discrete versions of the continuous nonlinear Schrödinger equation (NLS): the non-integrable discrete NLS equation (DNLS) with on-site nonlinearity and the integrable Ablowitz-Ladik (AL) equation with intra-site nonlinearity. Here by q -deformed, we mean the existence, both in the Poisson bracket (commutator in the quantum case) and in the Hamiltonian, of a free parameter q that allows “tuning” the nonlinearity (interaction) of the lattice model. From a physical point of view this equation represents a generalization of the tight-binding Schrödinger model

$$i \frac{dA_j(t)}{dt} + \Omega_j A_j(t) + J_j (A_{j+1}(t) + A_{j-1}(t)) = 0, \quad (1)$$

for the propagation of a molecular excitation in a crystal. Here A_j denotes the quasi-classical complex mode amplitude of a particular molecular vibration, Ω_j is the on-site frequency of this vibration, and J_j is the next-neighbor resonance interaction energy. Equation (1) was considered by Richard Feynman as a starting point for an alternate formulation of quantum mechanics in terms of coupled probability amplitudes (Feynman, 1965) (also it is equivalent to the Schrödinger equation for the description of the wave function of an electron in a perfect crystal in the tight-binding approximation). By assuming the coupling of the mode amplitudes to low-frequency phonons (lattice distortions), one obtains, in the adiabatic and small field amplitude approximation, a dependence of the local

energy and intra-site interaction upon A_j of the type

$$\begin{aligned} \Omega_j &\rightarrow \Omega_{0j} + \Omega_{1j}|A_j|^2, \\ J_j &\rightarrow J_{0j} + J_{1j}|A_j|^2. \end{aligned} \quad (2)$$

The Salerno equation follows by substituting the above relations into Equation (1) and redefining parameters as

$$\varepsilon = \frac{\Omega_1}{J_0}, \eta = \frac{\Omega_1}{J_1}, \omega_j = \frac{2J_0 + \Omega_0}{J_0}, \gamma = \frac{2J_1 + \Omega_1}{J_0},$$

thus giving

$$i \frac{dA_j(t)}{dt} - (2 - \omega_j - \varepsilon |A_j|^2) A_j + (1 + \frac{\varepsilon}{\eta} |A_j|^2) (A_{j+1} + A_{j-1}) = 0, \quad (3)$$

where time has been rescaled by a factor J_0 and equal local energies and intra-site resonance interactions were assumed (note that ω_j can be eliminated from Equation (3) by a rescale of time, so that in the following, we will put $\omega_j = 0$). With the above parametrization the following relationship between ε and η was introduced:

$$q \equiv \frac{\varepsilon}{\eta} = \frac{\gamma - \varepsilon}{2}. \quad (4)$$

This allows interpolation between the DNLS and the AL lattice as discussed below. To this end, it is worth noting that Equation (3) is a Hamiltonian system with respect to the following q -deformed Poisson bracket:

$$\begin{aligned} \{f, g\}_q &= \sum \left(\frac{\partial f}{\partial A_j} \frac{\partial g}{\partial A_j^*} - \frac{\partial g}{\partial A_j} \frac{\partial f}{\partial A_j^*} \right) \\ &\quad \times (1 + q |A_j|^2), \end{aligned} \quad (5)$$

and with Hamiltonian

$$\begin{aligned} H &= - \sum_j \left\{ A_j^* (A_{j+1} + A_{j-1}) + \eta |A_j|^2 \right. \\ &\quad \left. - \frac{(2 + \eta)}{\log(1 + \frac{\varepsilon}{\eta})} \log(1 + \frac{\varepsilon}{\eta} |A_j|^2) \right\}. \end{aligned} \quad (6)$$

It is easy to check that Equation (3) is obtained from Equations (5) and (6), as $i(dA_j/dt) = \{A_j, H\}_q$. Two values of the deformation parameter are of particular interest.

Case $q = 0$. This corresponds to the limit $\varepsilon \rightarrow \gamma$ for which the Poisson bracket acquires canonical form and Hamiltonian (6) becomes

$$-\sum_j \left\{ A_j^* (A_{j+1} + A_{j-1}) - 2|A_j|^2 - \frac{\gamma}{2} |A_j|^2 \right\}.$$

Equation (3) then reduces to the DNLS equation

$$i \frac{dA_j(t)}{dt} + A_{j+1} - 2A_j + A_{j-1} + \gamma A_j |A_j|^2 = 0, \quad (7)$$

which conserves the number $N = \sum_j |A_j|^2$ and allows solitary wave propagation (Scott, 2003). Although it is non-integrable, the DNLS equation is linked to many physical problems, from propagation of self-trapped modes in biomolecules and in arrays of nonlinear optical fibers, to the tight-binding description of Bose–Einstein condensates in optical lattices.

Case $q = \frac{\gamma}{\varepsilon}$. This corresponds to the limit $\varepsilon \rightarrow 0$ for which Equation (3) reduces to the Ablowitz–Ladik equation

$$i \frac{dA_j(t)}{dt} + A_{j+1} - 2A_j + A_{j-1} + \frac{\gamma}{2} \times (A_{j+1} + A_{j-1}) |A_j|^2 = 0, \quad (8)$$

which is known to have exact soliton solutions, being integrable by the Inverse Scattering Method (Scott, 2003).

The property of Salerno's equation to incorporate the above discrete versions of the NLS equation makes it an ideal general model to investigate the interplay between on-site and intra-site nonlinearity, discreteness and continuum, integrability and non-integrability. Studies performed along these lines during the past decade have shown the existence of a rich and wide range of behaviors, ranging from the existence of states localized on few lattice sites (intrinsic localized modes or discrete breathers), to the possibility of shock wave formation (Cai et al., 1994; Kivshar & Salerno, 1994; Konotop & Salerno, 1997; Mackay & Sepulchre, 2002). The existence of an integrable limit of the model also allowed clarification of the relation between intrinsic localized modes and exact discrete solitons of the AL lattice.

Signatures of these classical properties exist in the corresponding quantum model whose Hamiltonian is defined from Equation (6) as

$$\hat{H} = - \sum_j \left\{ \hat{b}_j^\dagger (\hat{b}_{j+1} + \hat{b}_{j-1}) + \eta \hat{b}_j^\dagger \hat{b}_j \right\},$$

$$- \frac{2 + \eta}{\log(1 + \frac{\varepsilon}{\eta})} \log \left[1 + \frac{\varepsilon}{\eta} \hat{b}_j^\dagger \hat{b}_j \right] \right\}, \quad (9)$$

where complex mode amplitudes A_j , A_j^* were replaced by creation and annihilation operators $\hat{b}_j$, $\hat{b}_j^\dagger$. Equation (5) implies the following deformed Heisenberg algebra:

$$\begin{aligned} [\hat{b}_i, \hat{b}_j^\dagger] &= \delta_{i,j} (1 + q \hat{b}_i^\dagger \hat{b}_i), \\ [\hat{b}_i, \hat{b}_j] &= [\hat{b}_i^\dagger, \hat{b}_j^\dagger] = 0, \end{aligned} \quad (10)$$

with the same q as in Equation (4). Note that the on-site algebra in Equation (10) is the same as the algebra of a q -oscillator (MacFarlane, 1989), thus providing an example of occurrence of a quantum deformation algebra in a physical model. An explicit representation of the q -algebra associated with the Salerno equation can be constructed as (Salerno, 1992; Bogoliubov & Bullough, 1992)

$$\begin{aligned} b^\dagger |n\rangle &= \sqrt{[n+1]_q} |n+1\rangle, \\ \hat{b} |n\rangle &= \sqrt{[n]_q} |n-1\rangle \end{aligned} \quad (11)$$

with $[n]_q = ((1+q)^n - 1)/q$. From this equation, it follows that the number operator is given by

$$\hat{N} = \sum_j \frac{\log(1 + \frac{\varepsilon}{\eta} \hat{b}_j^\dagger \hat{b}_j)}{\log(1 + \frac{\varepsilon}{\eta})}. \quad (12)$$

The conservation of $[\hat{N}, \hat{H}] = 0$, and the translational invariance of the system, $[\hat{T}_j, \hat{H}] = 0$ (T_j are translation operators by j sites along the lattice), allows one to block diagonalize the Salerno Hamiltonian into subspaces with fixed $\hat{N}$ eigenvalues and with fixed crystal momentum k . As for the classical model, the two limiting cases $\varepsilon = \gamma$ and $\varepsilon = 0$ correspond to the quantum DNLS lattice and to the quantum Ablowitz–Ladik system, respectively, the latter being integrable by means of the algebraic Bethe ansatz (Scott, 2003). By tuning the deformation parameter, one can get interesting physical behaviors. Thus, for example, for $q = -2$, the first commutator in Equation (10) becomes an anticommutator, so that the model describes a system of bosons with hard-core interactions (no more than one boson on a site). In this case, it was proved that in the mean field approximation (unconstrained hopping) and in the thermodynamic limit, the case $\varepsilon = 0$ displays a Bose–Einstein condensation (Salerno, 1994).

Exact diagonalizations of Equation (9) have been performed mainly for finite size and for finite number of quanta. Figure 1a depicts a typical band structure of Salerno's model in the reduced zone scheme for a chain of 15 sites, $N = 5$, $\gamma = 10$, and $\varepsilon = 5$. For

Figure 1. (a) Band structure of Salerno's model in the reduced zone scheme for a chain of 15 sites with $N=5$, $\gamma=10$, and $\varepsilon=5$. (b) Energy of the states with crystal momentum $k=0$, corresponding to the translational symmetry of the ground state, as a function of ε . Other parameters are fixed as (a).

these parameter values, the lower band corresponds to a bound state in which the five quanta are, with high probability, all on the same site. Figure 1b shows the energy of the states with crystal momentum $k=0$ (corresponding to the translational symmetry of the ground state) as a function of ε . Note that the minimum ground state energy is achieved for an ε value in between the AL ($\varepsilon=0$) and the DNLA case ($\varepsilon=10$).

The presence of an integrable limit of the Salerno model gives the possibility of exploring complicated properties of this quantum many-body system starting from the exact knowledge of its integrable limit. An interesting open problem in this direction is the characterization of the quantum analogue of a discrete breather of the corresponding classical model (discrete quantum breather). Work in this direction is presently under investigation.

SANDPILE MODEL

The concept of self-organized criticality (SOC) was introduced by Bak et al. (1987) using the example of a sandpile. If a sandpile is formed on a horizontal circular base with any arbitrary initial distribution of sand grains, a sandpile of fixed conical shape (steady state) is formed by slowly adding sand grains one after another (external drive). In the steady state, the surface of the sandpile makes on average a constant angle with the horizontal plane, known as the angle of repose. The addition of each sand grain results in some activity on the surface of the pile: an avalanche of sand mass follows, which propagates on the surface of the sandpile. In the stationary regime, avalanches are of many different sizes, and Bak et al. (1987) argued that they would have a power law distribution. If one starts with an initial uncritical state, initially most of the avalanches are small, but the range of sizes of avalanches grows with time. After a long time, the system arrives at a critical state, in which the avalanches extend over all length and time scales (Bak, 1996; Jensen, 1998; Dhar, 1999; Sornette, 2004).

Laboratory experiments on sandpiles, however, have not in general shown evidence of criticality in sandpiles due to the effects of inertia and dilatation (moving grains require more space) (Nagel, 1992), except for small avalanches (Held et al., 1990) or with elongated rice grains (Malte-Sørensen et al., 1999) where these effects are minimized. Small avalanches have small velocities (and thus negligible kinetic energy), and they activate only the first surface layer of the pile. Elongated rice grains slip at (or near the surface as a result of their anisotropy (thus minimizing dilatational effects), and they also build up scaffold-like structures, which enhance the threshold nature of the dynamics.

On the theoretical front, a large number of discrete and continuous sandpile models have been studied. Among them, the so-called abelian sandpile model is the simplest and most popular (Dhar, 1999). Other variants include Zhang's model, which has modified rules for sandpile evolution (Zhang, 1989), a model for abelian distributed processors and other stochastic rule models (Dhar, 1999), and the Eulerian Walkers model (Prietzhev et al., 1996).

In the abelian sandpile model, each lattice site is characterized by its height h . Starting from an arbitrary initial distribution of heights, grains are added one at a time at randomly selected sites n : $h_n \rightarrow h_n + 1$. The sand column at any arbitrary site i becomes unstable when h_i exceeds a threshold value h_c and topples to reduce its height to $h_i \rightarrow h_i - 2d$, where d is the space dimension of the lattice. The $2d$ grains lost from the site i are redistributed on the $2d$ neighboring sites $\{j\}$, which gain a unit sand grain each: $h_j \rightarrow h_j + 1$. This toppling may make some of the neighboring sites unstable. Consequently, these sites will topple themselves, possibly making further neighbors unstable. In this way, a cascade of topplings propagates, which finally terminates when all sites in the system become stable. When this avalanche has stopped, the next grain is added on a site chosen randomly. This condition is equivalent to assuming that the rate of adding sand is much slower than the natural rate of relaxation of the system. The large separation of the driving and of the relaxation time scales is usually considered to be a defining characteristic of SOC. Finally, the system must be open to the outside; that is, it must dissipate energy or matter, for instance. An outgoing flux of grains must balance the incoming flux of grains, for a stationary state to occur. Usually, the outgoing flux occurs on the boundary of the system: even if the number of grains is conserved inside the box, it loses some grains at the boundaries. Even in a very large box, the effects of the dissipating boundaries are essential: increasing the box size will have the effect of lengthening the transient regime over which the SOC establishes itself; the SOC state is built from the long-range correlations that establish a delicate balance between internal avalanches and avalanches that touch the boundaries (Middleton & Tang, 1995).

The simplicity of the abelian model is that the final stable height configuration of the system is independent of the sequence in which sand grains are added to the system to reach this stable configuration (hence the name “abelian” referring to the mathematical property of commutativity). On a stable configuration $\mathcal{C}$, if two grains are added, first at i and then at j , the resulting stable configuration $\mathcal{C}'$ is exactly the same as in the case where the grains were added first at j and then at i . In other sandpile models, where the stability of a sand column depends on the local slope or the local curvature, the dynamics is not abelian, since toppling of one unstable site may convert another unstable site to a stable site. Many such rules have been studied in the literature (Manna, 1991; Kadanoff et al., 1989).

An avalanche is a cascade of topplings of a number of sites created by the addition of a sand grain. The strength of an avalanche can be quantified in several ways:

- size (s): the total number of topplings in the avalanche,

- area (a): the number of distinct sites that toppled,
- lifetime (t): the duration of the avalanche, and
- radius (r): the maximum distance of a toppled site from the origin.

These four different quantities are not independent and are related to each other by scaling laws. Between any two such measures x, y belonging to the set $\{s, a, t, r\}$, one can define a mutual dependence by the scaling of the expectation of one quantity y as a function of the other x :

$$\langle y \rangle \sim x^{\gamma_{xy}}, \quad (1)$$

where γ_{xy} is called a critical exponent, index, or dimension. This equation quantifies a nonlinear generalized proportionality between the two observables x and y ($\ln(y)$ is proportional to $\ln(x)$). The exponents γ_{xy} are related to one another, for example,

$$\gamma_{ts} = \gamma_{tr} \gamma_{rs}. \quad (2)$$

For the abelian sandpile model, it can be shown that the avalanche clusters cannot have any holes and in addition that $\gamma_{rs} = 2$ in two dimensions, that is,

$$\langle s \rangle \sim r^2. \quad (3)$$

In words, the size (number of toppling grains) of an avalanche is proportional to its surface. It has also been shown that $\gamma_{rt} = \frac{5}{4}$:

$$\langle t \rangle \sim r^{\frac{5}{4}}; \quad (4)$$

that is, the average duration (t) of an avalanche grows with its typical radius r faster than linearly. However, averages reflect only a part of the rich behavior of sandpile models. A significant information is provided by the full distribution function $P(x)$ for any measure $x \in \{s, a, t, r\}$. Associated with the above scaling laws (1) and (2), one often finds the finite size scaling form for $P(x)$:

$$P(x) \sim x^{-\tau_x} f_x\left(\frac{x}{L^{\sigma_x}}\right). \quad (5)$$

The exponent σ_x determines the variation of the cut-off of the tail of the distribution of the quantity x with the system size L . As long as $x < L^{\sigma_x}$, expression (5) describes a power law distribution of x , reflecting a self-similar structure of the set of avalanches. When x becomes comparable with L^{σ_x} , the function f_x ensures a fast fall-off of $P(x)$ describing the impact of the finite size L of the system on the statistics of the fluctuations of x . Scaling relations like $\gamma_{xy} = (\tau_x - 1)/(\tau_y - 1)$ connect any two measures. Scaling assumptions (5) for the avalanche sizes have not been demonstrated and may be open to doubt (Kadanoff et al., 1989). This seems to be due to the effect of rare large avalanches dissipating at the border, which strongly influence the statistics.

Many different sandpile models have been studied. However, the precise classification of various models

into different universality classes in terms of their critical exponents is not yet available. Exact values of all the critical exponents of the most widely studied abelian model are still not known in two dimensions. Some effort has also been made toward the analytical calculation of avalanche size exponents (Kitarev & Priezzhev, 1998). Blanchard et al. (2000) have developed a dynamical system theory for a certain class of SOC models (like Zhang's model, 1989), for which the whole SOC dynamics can either be described in terms of iterated function systems, or as a piecewise hyperbolic dynamical system of skew-product type where one coordinate encodes the sequence of activations. The product involves activation (corresponding to a kind of Bernoulli shift map) and relaxation (leading to contractive maps).

In summary, the sandpile model of Bak et al. (1987) and its many extensions have helped found the new concept of self-organized criticality, which is now a useful item in the toolbox and set of concepts used to study complex systems involving triggered activities.

SCHEIBE AGGREGATES

Scheibe aggregates (also called J-aggregates) are a type of Langmuir–Blodgett thin films that were independently discovered in 1936 by Günther Scheibe (Scheibe, 1936) in Germany and E.E. Jelly (Jelly, 1936) in England—hence their names. They comprise compact and regular arrangements of dye molecules composed of chromophores and fatty acids that can be designed to pre-selected specifications. These molecular monolayers exhibit very efficient light capture followed by energy transfer to acceptor molecules present in the film at very low acceptor-to-donor ratios (as low as 1:10,000), giving the efficiency of energy transfer to acceptors as high as 50% (Moebius, 1989).

In the late 1960s and in the 1970s, Kuhn, Moebius and co-workers (Czikkelly et al., 1969) studied the effects of irradiation with ultraviolet or visible light and measured the strongly quenched donor fluorescence in these aggregates. An acceptor fluorescence line appeared whose amplitude was almost equal to that of the primary donor spectral line, but its peak was slightly redshifted, which was interpreted as evidence that the aggregate acts as a cooperative molecular array. After absorbing a photon, the energy moves in the form of an exciton traveling laterally over distances of up to 100 nm to a particular acceptor dye in the vicinity. The efficiency of this energy transfer mechanism is strongly linked with the rigidity of the aggregate and its regular order. Surprisingly, the capture of energy by an acceptor molecule improves with the ambient temperature. Optimal efficiency is achieved at fairly low acceptor-to-donor ratios as mentioned above.

Numerous technological applications of these molecular systems have been developed, including photographic and photo-detection processes as well as solar energy cell components (Inoue, 1985).

Several theoretical models of Scheibe aggregates have been developed over the years. The Frenkel exciton picture with the inclusion of diagonal disorder in molecular chains with nearest-neighbor interactions was adopted to describe the pseudo-isocyanine aggregate (Knapp, 1984) and was later extended to account for off-diagonal disorder. Subsequently, linear models of exciton propagation in the presence of shallow impurity potentials at acceptor sites showed (Bartnik et al., 1992) close quantitative agreement with experiment. These impurity potentials were usually assumed to be

of a square-well type, and their depth and spatial extent were parameters subject to optimization schemes. Interestingly, shallow impurity levels gave better capture properties than deep ones.

There have also been a number of theoretical studies advocating a role played by nonlinearity in the propagation of excitonic modes in Scheibe aggregates. The main reason for this claim is due to exciton-phonon coupling whose strength for mero-cyanine was experimentally determined as approximately $\chi = 29$ meV (Inoue, 1985) and theoretically estimated as $\chi = 26$ meV (Spano et al., 1990).

In general, three types of excitonic models can be applied: (a) a nearly free delocalized case, (b) a small polaron limit, and (c) the nonlinear self-trapped exciton state. The applicability criterion for these models involves a phase diagram in terms of two characteristic parameters: $g = \pi \chi^2 / \omega J$ and $\gamma = \hbar \omega / 2\pi J$, where h is Planck's constant, ω is the phonon frequency, and J is the exciton hopping constant. With the phonon energy approximately 30 meV, J in the range between 50 and 150 meV, and the exciton-phonon coupling constant ranging from 25 to 100 meV, the outcome of this parameter determination is yet inconclusive (Tuszyński et al., 1999).

It is important to stress that these systems should be modeled as two-dimensional structures. Continuous two-dimensional models with nonlinear terms have been developed that treat phonons classically and effectively eliminate them via an adiabatic approximation (Huth et al., 1989), leading to a 2-d radially symmetric cubic nonlinear Schrödinger equation, where the energy transfer takes place through soliton-like ring waves with a characteristic collapse time signifying the exciton lifetime. More recent models involving nonlinear equations of the cubic Schrödinger type also account for the presence of Gaussian impurity potentials (Christiansen et al., 1998).

Finally, it is necessary to include radiative losses in modeling the propagation of an exciton domain. Formally, this can be accomplished by adding an imaginary term to the exciton-phonon part of the Hamiltonian that describes the corresponding loss of energy of excitons as they collide with phonons in the thin-film lattice. Consequently, it has been shown that the rate of excitonic energy loss by a coherent exciton domain covering an area composed of N molecules is proportional to its size, N , and can be expressed as: $k_{\text{rad}} = N \text{ nanoseconds}^{-1}$. It has also been demonstrated that the characteristic time for radiative losses is approximately proportional to the absolute temperature T divided by 3000 K, and the result is expressed in nanoseconds (Moebius & Kuhn, 1988). In other words, the radiative decay time in nanoseconds is given by $\tau_{\text{rad}} = (T/3000)$ K. For example, at room temperature, a coherent exciton domain composed of 100 lattice sites has a decay time of 0.1 ns = 100 ps

compared with a flight time of only 2 ps, which means that radiative losses will not destroy the coherence of the exciton domain unless it is very large (approximately 10,000 lattice sites). A comprehensive review of the key processes taking place in exciton energy transfer in Scheibe aggregates (time of flight, radiative losses, exciton-phonon interaction, and diffusion on the 2-d lattice) can be found in Tuszyński et al. (1999).

SCROLL WAVES

Introduction

Scroll waves, which are observed in excitable media, can be imagined as a continuation of two-dimensional spiral waves to three dimensions. Spiral and scroll waves distribute frequency behavior to the two- and three-dimensional space, respectively, with the exception of a small subset of that space. For spiral waves this subset comprises the vicinity of a point and is called a core, whereas in three dimensions it is formed by the vicinity of a curve and is called a filament. In both cases, this exceptional subset acts as a source of waves that organizes the exhibited periodic or quasi-periodic frequency behavior; therefore, it is often referred to as an organizing center.

The intersection of the three-dimensional excitable medium containing a scroll wave with a plane that is locally perpendicular to the filament corresponds to a sheet in which a spiral wave rotates, showing the close relationship between these two types of excitation waves. But because curves (the filaments) can have complex geometrical and topological properties, the behavior of scroll waves turns out to be much more complicated than that of spirals.

Early work on rotating excitation waves was performed on physical rings of heart tissue (quasi-one-dimensional systems), where an electrical impulse can propagate around a hole without attenuation for days. The importance of this observation lies in the complex anatomy of the heart: in particular, the orifices from arteries make the surface of the heart locally similar to physical rings and, therefore, allow for the so called circus-movement reentry, that is, electrical excitation waves circulating around inhomogeneities. Modeling of this phenomenon was undertaken first by Norbert Wiener and Arturo Rosenbluth in 1946. Periodic excitation was found to be also possible in media without holes, that is, in quasi-two-dimensional media. The electrical excitation wave (see Figure 1) then assumes the shape of a spiral (Tyson & Keener, 1988). The importance of the third dimension was recognized when performing experiments with the excitable Belousov–Zhabotinsky reaction system (See **Belousov–Zhabotinsky reaction**), since distortions and other unexpected behavior of spiral waves in presumed two-dimensional shallow layers could be readily explained when assuming a non-uniform excitability along the small but nonnegligible vertical direction (see references in Winfree, 1987).

For the theoretical treatment of scroll waves there are several models that are most commonly used.

Figure 1. A scroll wave on the surface of a heart. (Image from Panfilov & Pertsov, 2001.)

Since scroll waves are structures appearing in excitable media, it is not surprising that they have been investigated by using three-dimensional FitzHugh–Nagumo equations, that is, a two-variable model designed for the simulation of neural action potentials (See **FitzHugh–Nagumo equation**). It was found that scroll waves always undergo twist (see below) when entering inhomogeneous media (Mikhailov et al., 1985).

Another model for the investigation of scroll waves is the Oregonator model derived from the reaction kinetics of the Belousov–Zhabotinsky reaction. The temporal development of a scroll ring, a structure with a closed filament not touching the boundary (see Figure 2, and also Welsh et al., 1983), was investigated by Winfree and Jahnke in 1989. It was found that a scroll ring decreases its size in the course of time and eventually vanishes, showing that scroll waves are topologically distinct from spirals.

A now very popular model is the so-called Barkley model, well known for its computational efficiency. Originally introduced for the investigation of the meander instability of spiral waves (Barkley, 1990), it is also used for investigating scroll waves. With this model it was possible to classify the instabilities of scroll waves in isotropic excitable media (Henry & Hakim, 2002).

While these three models give a description of the full three-dimensional concentration distribution, a fourth one deals with the geometry of an iso-concentration level. Its formulation is based on the eikonal equation, which expresses the relationship between the curvature and the normal velocity of a surface defined by such a level. Thus, the surface is described in specific coordinate systems that reflect the topological situation of the filaments involved in the

Figure 2. A scroll ring in a test tube, inner diameter: 10 mm. (Image from Winfree, 1987.)

wave structure. Investigating this type of model allows one to estimate the stability of complex, linked wave structures (McDermott et al., 2002).

Complexity of Scroll Waves

The complexity of a scroll wave becomes apparent when one imagines such a wave structure extending into a nonhomogenous excitable medium, that is, when in each slice along the filament the rotation period of the spirals is intrinsically different. Without a coupling mechanism, the phase of the spirals in these adjacent slices would evolve independently, and the differences between the phases would diverge. This is not possible, and the wave structure circumvents this inconvenience by tilting the wave fronts emanating from the organizing center. In terms of the rotation phases of the spirals, this corresponds to a phase shift along the filament, which is called twist.

While the twist takes arbitrary values in the case of scroll waves (organized by filaments reaching from one boundary of the medium to another), it has to fulfill quantization conditions for scroll rings. The first limitation is that the twist of a scroll ring along one

Figure 3. An example of an impossible surface of a wave structure. (Image from Winfree, 1987.)

Figure 4. Decomposition of a scroll wave due to a gradient of excitability. (Image from Strob et al., 2003.)

turn along the filament has to be a multiple of 2π . A further limitation for the possible structures arises from the constraint that the surface must not have any intersections (i.e., it has to be a Seifert-surface, see Figure 3 for an impossible surface). This, for example, excludes single scroll rings of twist 2π . Instead, these always must appear as linked pairs, although in the limiting case one of them may be infinitely large or may reach from one boundary to the other (Winfree, 1987). More elaborate work on the topology and geometry of filaments has been summarized by Tyson and Strogatz (1991).

Although the computational investigation of scroll waves started in the 1980s, about ten years after their discovery, rigorous experimental research on

three-dimensional wave structures did not begin before the 1990s. First measuring techniques were restricted to simple projections from one, two, or three pairwise orthogonal directions.

Three-dimensional, fully resolved observations of scroll waves and rings have been performed by optical tomography since about 1995. This technique allows one to record and evaluate time and space resolved data sequences. For instance, the decomposition of a scroll wave due to a gradient of excitability was observed in satisfactory detail (see Figure 4). Thus, experimental and theoretical tools are now available to investigate the complex interaction of the organizing centers of scroll waves.

SEMICONDUCTOR LASER

The semiconductor laser is today the most important and widespread type of laser, being a central component in many common household appliances (CD and DVD players) as well as in major industrial areas, such as measurement and sensing, materials manufacturing, and medical surgery. Not least, the semiconductor laser has enabled the rapid evolution of the Internet by providing a means for efficient and cheap conversion of digital electrical signals into optical signals, which can be transmitted at very high data rates and over very long distances in hair-thin optical fibers.

The success of the semiconductor laser to a large degree relies on its many similarities with electronic semiconductor devices such as transistors and diodes. The laser is manufactured by standard semiconductor crystal growth and processing techniques, allowing for small and cheap devices. Furthermore, the semiconductor laser distinguishes itself from other types of lasers by being electrically activated. Thus, the energy needed for pumping the laser to an excited state, from which the energy can be released by emission of photons, is achieved simply by putting direct electrical current through the device. Other kinds of lasers typically need some kind of optical pumping for populating the laser-active states.

Figure 1 shows a schematic of a typical semiconductor laser. The laser is a p–i–n structure; that is, p- and n-doped semiconductor materials sandwich an undoped intrinsic (“i”) region. The structure acts as a standard pn-junction diode; when forward biased (with a positive voltage on the metallized p-side relative to the n-side), an electrical current flows. This leads to the build-up of significant electron and hole densities in the intrinsic region, and by recombination of these excited-state (conduction-band) electrons with ground-state (valence-band) holes, photons can be generated. An incoming photon may thus stimulate the emission of a new photon with identical properties. This process of stimulated emission provides optical gain, which is

Figure 1. Schematic of a semiconductor laser. Light is confined to a waveguide of transverse dimension typically of the order of $0.2\text{ }\mu\text{m} \times 2\text{ }\mu\text{m}$. For a quantum well structure, stimulated emission occurs in a narrow region of width $\sim 100\text{ Å}$. The laser is pumped electrically by incorporating the active region in a pn-junction.

one of the two key requirements for implementing a laser.

As for any oscillator, the second requirement—besides gain—is the existence of feedback. For a laser, this is usually achieved by incorporating the gain medium in a mirror cavity. In the case of a semiconductor laser, the mirrors are particularly simple since cleaving along one of the crystal planes provides a naturally flat mirror with an intensity reflection coefficient of the order of 30%. Due to the large material gain achievable in semiconductor lasers, a laser-active region length of the order of a few hundred μm is sufficient to compensate for the corresponding 70% outcoupling loss, as well as other losses in the material, thus enabling laser oscillation.

In addition to providing feedback, the laser cavity also must confine the optical laser mode in the transverse plane. This is achieved by establishing a transverse waveguide through index-guiding. The design thus needs to ensure a larger effective index in the active region of the laser as compared with the surrounding regions. In the growth direction, index guiding is provided by use of a so-called semiconductor heterostructure. The intrinsic, “i”-region is thus composed of a material with a smaller bandgap than the surrounding materials, which leads to a larger refractive index. The incorporation of a heterojunction structure was a major achievement in the early development of semiconductor lasers and earned the inventors, Zhores Alferov and Herbert Kroemer, the Nobel Prize in Physics in 2000. Besides providing index confinement, the heterostructure also ensures efficient collection of electrons and holes in the active region.

Index guiding in the plane (lateral direction) of the semiconductor layers is more difficult and is achieved in a number of different ways, the two most important ones employing a ridge waveguide structure and a buried heterostructure. The ridge waveguide structure is obtained by processing a narrow ridge ($1\text{--}2\text{ }\mu\text{m}$ wide) in the doped semiconductor material topping the active region. The material that is etched

away on either side of the ridge is replaced by a material (e.g., polyimide) that is isolating and has an index of refraction less than that of the semiconductor (ca. 3.5). The ridge provides current confinement and leads to an effective refractive index that varies in the lateral direction along the active region, reaching a maximum value right below the high-index ridge, thus imposing lateral waveguiding. The refractive index contrast thus obtained is, however, modest, and ridge waveguide lasers belong to the class of weakly index-guided structures. The other class of strongly index-guided structures is exemplified by the buried heterostructure laser. By employing several growth steps, the active waveguide region can thus be surrounded, in the lateral direction, by materials with higher bandgap and lower refractive index. Furthermore, these regions, adjacent to the active region, are doped to block the current from entering.

By analogy with a standard laser cavity (etalon), a semiconductor laser using cleaved facets to define the laser cavity is denoted a Fabry–Perot laser. Due to the small difference in material gain between the longitudinal modes of such a laser cavity, the laser may oscillate in several closely spaced modes and the single-mode suppression ratio remains modest. By incorporating a grating structure in the laser, either distributed over the entire waveguide length (distributed feedback or DFB laser) or localized close to the facets (distributed Bragg reflector or DBR laser), spectral selection can be achieved, resulting in high-quality single-mode lasers. DFB lasers, in particular, have been successfully applied in optical communications systems. A more recent type of laser is the so-called vertical cavity surface emitting laser (VCSEL), where the laser end mirrors are provided by Bragg gratings parallel to the semiconductor substrate and the laser emits out of the plane of the substrate.

The choice of the materials for the active region determines the wavelength of the output optical beam. Two materials systems are particularly important: GaAlAs lasers, which cover the wavelength range of 700–900 nm, and InGaAsP lasers, which cover the wavelength range of 1000–1600 nm. The latter laser type is the most important for long-distance optical communication systems due to the low loss and/or dispersion of optical fibers in the range of 1300–1550 nm. An additional degree of freedom comes from employing a so-called quantum well structure of the active layer. Thus, by incorporating thin (about 5–10 nm) layers of semiconductor with a bandgap lower than the surrounding (barrier) material in the active region, quantum confinement effects change the allowed energy levels of electrons. This leads to a change in the effective bandgap of the laser (wavelength under lasing), as well as the number of electrons needed to reach population inversion.

Quantum well lasers have achieved low-threshold and high-power operation. Quantum dot lasers, employing three-dimensional quantum confinement of electrons, offer excellent electron control and have led to lasers with record low-threshold current density. However, semiconductor growth technology has not yet (in 2004) matured to the point of offering full control of quantum dot sizes.

The laser threshold condition and the basic features of the laser dynamics are captured by a simple set of rate equations describing the temporal evolution of the photon density, P , and the carrier density, N (Coldren & Corzine, 1995):

$$\frac{dP}{dt} = (\Gamma v_g g - \tau_p^{-1})P + \Gamma \beta_{sp} R_{sp}, \quad (1)$$

$$\frac{dN}{dt} = \frac{I}{eV} - \frac{N}{\tau_s} - v_g g P. \quad (2)$$

Here, v_g is the group velocity; τ_p is the photon lifetime, its inverse being the rate at which photons are lost from the laser cavity; β_{sp} is the rate of spontaneous emission; ending up in the lasing mode; I is the injected current; e is the electronic charge; V is the active region volume; and τ_s is the carrier lifetime. The confinement factor, Γ , expresses the fraction of the optical mode that overlaps with the active region; it may also be expressed as the ratio between the active region volume, V , and the effective volume of the optical mode, V_{opt} . In the form of the equations stated above, the photon density is normalized with respect to V_{opt} , whereas N is normalized with respect to V . Finally, g is the material gain. When considering a laser operating at the peak of the gain curve, it is, at least for lasers with bulk active regions, a good approximation to parameterize the gain as

$$g \cong g_N(N - N_0) \quad (3)$$

with g_N being the differential gain, and N_0 the carrier density at transparency. For $N = N_0$, we have $g = 0$, corresponding to the case where stimulated emission and absorption exactly balance. For a further increase of the carrier density, population inversion is achieved and the material gain is positive.

The rate equations (1) and (2) are basically book-keeping equations. Equation (2) expresses the effective pumping of electrons from valence to conduction band through the applied current. Due to spontaneous emission as well as nonradiative recombination (Auger processes are particularly important in long-wavelength lasers), the excited carrier density has a lifetime τ_s of the order of a nanosecond or less. Furthermore, stimulated emission, proportional to the product of the gain and the photon density, depletes the population of excited carriers, as expressed by the last term in Equation (2). That same process leads to a generation term in the rate equation for the photon density. Also, a certain fraction, β_{sp} , which may typically be of the order of 10^{-5} of the

total rate of spontaneous emission, R_{sp} , ends up in the laser mode and is accounted for by the last term in Equation (1). Finally, the drain term in Equation (1) describes all mechanisms by which photons are lost from the cavity, including output coupling at the mirror facets and internal loss (due to free-carrier absorption, waveguide scattering loss, etc.).

The steady-state solution of the rate equations, with the gain given by Equation (3), yields the light-current characteristics, laser power that is, expressed in terms of the photon density as a function of the applied current. A simple solution, yet accurate except very close to threshold, is obtained by neglecting the rate of spontaneous emission into the lasing mode, that is, the last term in Equation (1). A small-signal analysis shows that the above-threshold solution is a stable focus. The characteristic frequency is the so-called laser relaxation oscillation frequency, which is the natural frequency at which energy is exchanged between the carrier population and the photon population. The relaxation frequency is also a measure of the order of the maximum bit-rate at which a laser can be efficiently current-modulated to produce an intensity-modulated optical output signal. The square of the relaxation oscillation is approximately proportional to the laser output power, although the oscillations become strongly damped as the frequency increases. High-speed lasers have relaxation frequencies of the order of 30 GHz.

From the Kramers–Kronig relations, any change of the gain of a material (proportional to the imaginary part of the susceptibility) implies a change in the refractive index (proportional to the real part of the susceptibility). Due to the asymmetric nature of the gain spectrum of a semiconductor laser—with a transparent region below the bandgap of the material and a strongly absorbing region at large photon energies—the coupling between index and gain is particularly strong for semiconductor lasers, with profound consequences for the dynamics. This coupling is described by the so-called linewidth enhancement factor (or alpha-parameter) α . It was thus realized that the gain-index coupling gives rise to an enhancement of the linewidth of a semiconductor laser by a factor of $1 + \alpha^2$ (Henry, 1983), and also imposes a chirp on the optical signal under current modulation. These effects are not described by the rate equation (1), which only governs the magnitude squared of the electromagnetic (optical) field and is independent of the phase. Rather the dynamics need to be described by an equation for the complex electric field amplitude, E :

$$\frac{dE}{dt} = \frac{1}{2}(1 + i\alpha)\Gamma v_g g_N(N - N_0)E + F_E(t), \quad (4)$$

where $P \propto |E|^2$. The term $F_E(t)$ is a stochastic Langevin noise term accounting for the random nature of spontaneous emission. The amplitude and phase noise properties of single-mode semiconductor lasers can be analyzed based on Equations (3) and (2).

Addition of a feedback term, proportional to $E(t - \tau)$, to the right-hand side of Equation (3) leads to the famous Lang–Kobyashi equations (Lang & Kobyashi, 1980), which govern the dynamics of a semiconductor laser coupled to an external mirror, τ being the roundtrip time in the external cavity. The semiconductor laser with feedback displays very rich dynamics, including mode-hopping, various instabilities and chaos, that to a remarkable degree are explained by Equations (4) and (2) (Mørk et al., 1992).

The rate equation model outlined above is limited to the case of single transverse mode lasers. Wide aperture lasers, in contrast, have an additional degree of freedom in the transverse direction. It has been shown that a complex semiconductor Swift–Hohenberg equation may describe the dynamics of such lasers in a single longitudinal mode mean field limit (Mercier & Moloney, 2002).

SEMICONDUCTOR OSCILLATORS

The electric transport properties of a semiconductor show up most directly in its current-voltage characteristic. It is related to a relationship between the current density j and the electric field E that is determined in a complex way by the microscopic properties of the material. Although a local, static, scalar $j(E)$ relation need not exist, it does in many cases.

Close to thermodynamic equilibrium (at sufficiently low bias voltage), the $j(E)$ relation is linear (Ohm's law), but under practical operating conditions it often becomes nonlinear and may even display a regime of negative differential conductivity (NDC), where $\sigma_{\text{diff}} = dj/dE < 0$. The global current-voltage characteristic $I(U)$ of a semiconductor can in principle be calculated from the local $j(E)$ relation by integrating the current density j over the cross section A of the current flow and the electric field E over the length L of the sample. Unlike the $j(E)$ relation,

the $I(U)$ characteristic is not only a property of the semiconductor material, but depends also on the geometry, the boundary conditions, and the contacts of the sample. Only for the idealized case of spatially uniform states, are the $j(E)$ and the $I(U)$ characteristics identical, up to re-scaling. The $I(U)$ relation is said to display negative differential conductance if $dI/dU < 0$.

In the case of negative differential conductance, the current decreases with increasing voltage, and vice versa, which may lead to instability. The actual electrical response depends upon the attached circuit, which in addition to resistors may comprise capacitors and inductors. These reactive components give rise to additional degrees of freedom that are described by ordinary differential equations for I and U . If a semiconductor element with NDC is operated in such a reactive circuit, oscillatory instabilities may be induced by these reactive components. Self-sustained semiconductor oscillations, where the semiconductor itself introduces an internal unstable temporal degree of freedom, can be distinguished from those circuit-induced oscillations. The self-sustained oscillations under time-independent external bias are discussed here. Examples of internal degrees of freedom are the charge carrier density, the electron temperature, or a junction capacitance within the device.

Two important examples of NDC are described by an N -shaped or an S -shaped $j(E)$ characteristic and denoted by NNDC and SNDC, respectively (Figure 1). However, more complicated forms such as Z -shaped, loop-shaped, or disconnected characteristics are also possible. NNDC and SNDC are associated with voltage or current-controlled instabilities, respectively. In the NNDC case the current density is a single-valued function of the field, but the field is multivalued; in other words, the $E(j)$ relation has three branches in a certain range of j . The SNDC case is complementary in the sense that E and j are interchanged.

In case of NNDC, the NDC branch is often but not always (depending upon external circuit and boundary conditions) unstable against the formation of non-uniform field profiles along the charge transport direction (electric field domains). In the SNDC case, on the other hand, current filamentation generally occurs, in which the current density becomes non-uniform over the cross section of the current flow and forms a conducting channel (Ridley, 1963). These primary self-organized spatial patterns may themselves become unstable, leading to periodically or chaotically breathing, rocking, moving, or spiking filaments or domains, or even solid-state turbulence and spatiotemporal chaos (Schöll, 2001). Alternatively, the spatially uniform steady state may already become unstable with respect to uniform oscillations in a Hopf bifurcation.

Semiconductor oscillators may be classified as dominated by a bulk mechanism (drift instability,

Figure 1. Current density j versus electric field E for two types of negative differential conductivity (NDC): (a) NNDC; (b): SNDC (schematic).

generation-recombination instability) or by heterojunctions and potential barriers and wells (resonant tunneling across, or thermionic emission over, barriers in nanostructures).

The first class of semiconductor oscillators includes drift instability. In the simplest extension of the Drude model, the current density is given by $j(E) = -en v(E)$ where $e > 0$ is the electron charge, n is the electron density, and $v(E)$ is the field-dependent drift velocity, which may give rise to negative differential conductivity if $d|v|/d|E| < 0$. The best-known example is the Gunn effect, which is based upon intervalley transfer of electrons in k -space from a state of high mobility to a state of low mobility under a strong electric field in direct semiconductors like GaAs or other III-V compounds (Gunn, 1964; Ridley & Watkins, 1961). This phenomenon is used in real devices (Gunn diodes) to generate and amplify microwaves at frequencies typically beyond 1 GHz.

The class of generation-recombination (GR) instabilities is distinguished by a nonlinear dependence of the steady-state carrier concentration n upon the field E that yields a non-monotonic relation $j = en(E)\mu E$ of either NNDC or SNDC type, where μ is the mobility. This dependency is due to a redistribution of electrons between the conduction band and bound states with increasing field. The microscopic transition probabilities of the carriers between different states, and hence the GR coefficients, generally depend upon the electric field. Models of this type are relevant for a va-

riety of materials and in various temperature ranges (Schöll, 1987) and can explain SNDC and current filamentation in the regime of low-temperature impurity breakdown and self-generated current oscillations including chaotic behavior, as observed experimentally (Peinke et al., 1992). Two important devices are also based upon GR-induced bulk negative differential conductivity, but the coupling with junction effects is essential in these cases: p-i-n diodes and impact ionization avalanche transit-time (IMPATT) diodes.

A variety of instabilities can arise due to the specific transport properties of semiconductor heterostructures. One mechanism for NNDC, which is the real space analog of the k -space intervalley transfer in the Gunn effect, uses electron transfer between a high-mobility layer and a low-mobility layer in a modulation-doped semiconductor heterostructure under a time-independent bias applied parallel to the layers (Gribnikov et al., 1995). In the NNDC regime, current oscillations of 2–200 MHz have been experimentally observed and theoretically explained.

Another class of oscillatory instabilities occurs under vertical electrical transport in layered semiconductor structures, for example, in the heterostructure hot-electron diode (HHED) or the double-barrier resonant tunneling diode (DBRT), which are associated with S-shaped and Z-shaped current-voltage characteristics, respectively (Schöll, 2001). A resonant tunneling structure is composed of alternating layers of two different semiconductor materials with different bandgaps. The energy diagram shows a modulation of the conduction band edge on a nanometer scale, forming potential barriers and quantum wells. The current density across the barrier between two wells is due to quantum mechanical tunneling and exhibits a strongly nonlinear dependency upon the electric field. It is maximum if there is maximum overlap between the occupied states in one well and the available unoccupied states in the other (the energies are in resonance). For low-fields, equivalent levels in adjacent wells are approximately in resonance. With increasing field, the energies of the two wells are shifted with respect to each other, and the available states in the collecting well are lowered with respect to the emitting well, and hence the current density drops as the overlap between the energy levels decreases, thereby displaying NDC. Upon further increase of the field, the current density rises again up to a sharp resonance peak when the ground energy level in one quantum well is aligned with the second level in the neighboring well. Thus, resonant tunneling produces NNDC.

The simplest system of this type consists of a double-barrier structure with one embedded quantum well in between, sandwiched between a highly doped emitter and collector region. However, the situation becomes more complicated if the nonlinear feedback between space charges and transport processes is taken

into account. The built-up charge in the well leads to an electrostatic feedback mechanism that increases the energy of the well state supporting resonant tunneling conditions for higher applied voltages. This may result in bistability and hysteresis where a high current and a low current state coexist for the same applied voltage, and the current-voltage characteristic becomes Z-shaped. Switching between the two stable states as well as self-sustained current oscillations may occur under appropriate external circuit conditions. The bistability also provides a basis for lateral pattern formation (current filamentation) and spatiotemporal bifurcation scenarios including chaotic breathing and spiking.

Sequential resonant tunneling in a periodic structure of multiple quantum wells, a semiconductor superlattice, likewise displays NNDC (Esaki & Chang, 1974). Now, along the growth direction, the uniform field distribution may break up into a low-field domain, where the field is near the first peak of the $j(E)$ characteristic, and a high-field domain, where the field is close to the second, resonant-tunneling peak. Depending upon doping, the applied voltage, structural parameters, and the emitter contact conductivity, stationary or traveling domains occur—the latter leading to self-sustained current oscillations ranging from several hundred MHz up to 150 GHz at room temperature (Wacker, 2002).

SEPARATION OF VARIABLES

Separation of variables is the name of a general method for finding particular solutions of partial differential equations (PDEs) as a product of functions, where each factor depends on only one of the independent variables and satisfies an ordinary differential equation (ODE).

In the study of linear equations, a familiar example of the method is eigenfunction analysis. Using the superposition principle, this approach leads to expansions in products of orthogonal functions. The Fourier transform method is a special limiting case.

For a particular PDE, there may be a family of coordinate systems that admits separation of variables. The problem of finding such coordinate systems is closely connected with the group properties of differential equations. Methods from Lie group theory can be used to describe all the separable solutions of many equations from mathematical physics (Miller, 1977). In Morse and Feshbach (1953), the separable orthogonal coordinate systems for the Laplace, Helmholtz, Schrödinger, heat (diffusion), and wave equations in two and three dimensions are listed.

For example, Laplace's equation

$$u_{xx} + u_{yy} = 0 \quad (1)$$

has product solutions $u(x, y) = X(x)Y(y)$, where X (respectively, Y) is a function of only the independent variable x (respectively, y). Here X and Y satisfy the ordinary differential equations $X'' + \lambda X = 0$ and $Y'' - \lambda Y = 0$, where λ is the separation constant and prime denotes differentiation with respect to the independent variable. X and Y may thus be expressed in terms of trigonometric and exponential functions.

Separability depends on the boundary conditions. As a second example, consider the Helmholtz equation

$$u_{xx} + u_{yy} + k^2 u = 0 \quad (2)$$

in two dimensions with Dirichlet or Neumann boundary conditions ($u=0$ or $u_n=0$, where subscript n denotes the derivative in the direction normal to the boundary). This boundary value problem is separable in rectangular, parabolic, polar, and elliptic coordinates.

However, with the mixed (Robin) or impedance boundary condition $u_n + cu = 0$ (where the impedance c is a constant), the problem is only separable in rectangular and polar coordinates.

For nonlinear wave equations a method for separation of variables is sometimes called Lamb's method, stemming from an early analysis of the sine-Gordon (SG) equation (Lamb, 1971)

$$u_{xx} - u_{tt} - \sin u = 0. \quad (3)$$

This equation has solutions of the form $u(x, t) = 4 \tan^{-1}(X(x)T(t))$, where $(X')^2 = a_1 X^4 + a_2 X^2 + a_3$ and $(T')^2 = -a_3 T^4 + (a_2 - 1)T^2 - a_1$, and a_1, a_2 , and a_3 are separation constants. In general, therefore, X and T are Jacobi elliptic functions.

In special cases simpler SG soliton solutions such as kinks, antikinks, colliding kinks and antikinks, breathers or bions, and plasma waves, are obtained. For example, choosing $a_1 = a_2 = 1/(1 - v^2)$ and $a_3 = 0$ yields colliding kinks, traveling with velocities v and $-v$, respectively, while $a_2 = -a_3 = 1/(1 - v^2)$ and $a_1 = 0$ yields colliding kinks and antikinks. Since the SG equation models long Josephson junctions, fluxons traveling on Josephson junctions of infinite length are obtained as derivatives of the kinks (Scott, 2003), and nonlinear oscillations or standing waves on junctions of finite length can also be found for boundary conditions of Dirichlet or Neumann type (Costabile et al., 1978).

Separation of variables provides solutions to other nonlinear partial differential equations such as the nonlinear Schrödinger equation (NLS)

$$iu_t + u_{xx} + 2|u|^2 u = 0. \quad (4)$$

Writing $u(x, t) = \phi(x, t)e^{i\theta(x, t)}$, the amplitude function, $\phi(x, t)$, and the phase function, $\theta(x, t)$, satisfy nonlinear coupled ordinary differential equations that permit traveling wave solutions of the form $\phi(x, t) = \phi(x - vt)$, where v is the velocity. These are the NLS envelope solitons (Scott, 2003).

Standing wave solutions to the so-called improved Boussinesq equation

$$u_{xx} - u_{tt} - (u^2)_{xx} + u_{xxt} = 0 \quad (5)$$

of the form $u(x, t) = 1/2 + X(x)T(t)$, where $X(x)$ and $T(t)$ satisfy uncoupled nonlinear ordinary differential equations, have been obtained in Rosenau and Schwarzmeier (1986) and Christiansen et al. (1990).

The Hamilton–Jacobi equation is separable when Hamilton's characteristic function, W , can be written as a sum of functions where each function depends on only one of the independent variables (Goldstein, 1980). Let us look at a particle with mass m moving in central force with potential $V(r)$. Using polar coordinates (r, ϕ) in the plane of the orbit, the Hamiltonian has the form

$$H = \frac{1}{2m} \left(p_r^2 + \frac{p_\phi^2}{r^2} \right) + V(r), \quad (6)$$

and is cyclic in ϕ . Consequently, Hamilton's characteristic function

$$W = W_r(r) + W_\phi(\phi) \equiv W_r(r) + \alpha_\phi \phi, \quad (7)$$

where the momentum conjugated to r is $p_r = \partial W_r(r)/\partial r$ and the angular momentum conjugated to ϕ , $p_\phi = \partial W_\phi(\phi)/\partial \phi = \alpha_\phi$ is a constant. The Hamilton–Jacobi equation now becomes

$$\left(\frac{\partial W_r(r)}{\partial r} \right)^2 + \frac{\alpha_\phi^2}{r^2} + 2mV(r) = 2mE, \quad (8)$$

where E is the total energy of the system. Integrating (8) with respect to r , $W_r(r)$ and thus W given by (7) are obtained. The canonical equations then yield the orbitals in the form $r = r(t)$ or $r = r(\phi)$.

A new approach has been developed by Sklyanin (1995), who argues that separation of variables, understood generally enough, could be a universal tool to solve integrable models of classical and quantum mechanics. Standard construction of the action-angle variables for the poles of the Baker–Akheizer function can be interpreted as a variant of separation of variables. The new approach has been applied to magnetic chains, the Toda lattice, the nonlinear Schrödinger equation, the sine-Gordon model, and other systems (Sklyanin, 1995).

SHEAR FLOWS

Shear flows arise whenever two bodies of fluid move relative to each other, as in a jet of liquid entering a fluid at rest or the flow past a solid obstacle. When the flow speeds become too high, these flows undergo instabilities that are at the root of the vortical structures that dominate turbulent flows. For the Kelvin–Helmholtz; instability of two layers of fluid in relative motion; the instabilities of a fluid sheared between two concentric, rotating cylinders (Taylor–Couette flow); the dynamics of boundary layers; and viscous Hele–Shaw experiments, see the corresponding *Encyclopedia* entries.

Energy balance: The significance of shear as a source of energy for perturbations follows from the analysis of the energy content of a perturbation to a shear flow. Let $\mathbf{U}$ be a prescribed stationary flow in a domain V and let $\mathbf{u}$ be the perturbation added to $\mathbf{U}$. The Reynolds number is defined in terms of the velocity scale U of the reference flow, a length scale L , and the kinematic viscosity ν , that is, $\text{Re} = UL/\nu$. For a divergence free perturbation with boundary conditions $\mathbf{u} = 0$ on surfaces, the energy content $E(t) = \int_V dV (\mathbf{u}^2/2)$ satisfies the Orr–Reynolds equation

$$\frac{dE}{dt} = - \int_V u_i u_j \frac{\partial U_i}{\partial x_j} dV - \frac{1}{\text{Re}} \int_V \frac{\partial u_i}{\partial x_j} \frac{\partial u_j}{\partial x_i} dV. \quad (1)$$

Since the last term on the right-hand side is negative semidefinite, all the energy input has to come from the shear $\partial U_i / \partial x_j$. If the shear is too small, then $E(t)$ will decay monotonically. The Reynolds number up to which $\dot{E} \leq 0$ for all perturbations defines the energy stability limit Re_E .

Parallel flows: A necessary condition for an instability of parallel inviscid flows was derived by Lord Rayleigh (John William Strutt) in 1880; he found that instability requires an inflection point. If $\mathbf{u} = U(y)\mathbf{e}_x$ is the unperturbed profile, then instability can occur only if there is a point y_s with $U''(y_s) = 0$. This criterion was later improved by R.Fjrtoft, who found the requirement $U''(y)(U(y) - U(y_s)) < 0$. Necessary and sufficient conditions are more complicated, as discussed in Balmforth & Morrison (1999).

For the viscous stability, it is useful to represent the perturbation with components (u, v, w) in terms of the vertical velocity component v and the vertical

vorticity, $\eta = \partial_z u - \partial_x w$, and to expand in terms of Fourier modes,

$$v(x, y, z, t) = \tilde{v}(y)e^{i(\alpha x + \beta z - \omega t)}, \quad (2)$$

$$\eta(x, y, z, t) = \tilde{\eta}(y)e^{i(\alpha x + \beta z - \omega t)}. \quad (3)$$

Then the amplitudes satisfy

$$\left[(-i\omega + i\alpha U)(D^2 - k^2) - i\alpha U'' - \frac{1}{\text{Re}}(D^2 - k^2)^2 \right] \times \tilde{v} = 0, \quad (4)$$

$$\left[(-i\omega + i\alpha U) - \frac{1}{\text{Re}}(D^2 - k^2) \right] \times \tilde{\eta} = -i\beta U' \tilde{v}. \quad (5)$$

The first equation is the Orr–Sommerfeld equation, the second Squire's equation. In 1933, H.B. Squire showed that if there is an instability for a mode with spanwise wave number $\beta \neq 0$, then there is another one with $\beta = 0$ that has a lower Reynolds number, where instabilities set in without spanwise modulations.

The linearized problem can show transient growth: a decaying eigenstate of the Orr–Sommerfeld equation can drive the Squire equation and cause an amplification of the normal vorticity (if $\beta \neq 0$). The most effective modes often have the form of downstream vortices, with only slight modulations in spanwise and downstream direction. They drive spanwise modulations in the downstream velocity component, so-called streaks. Fabian Waleffe (1995, 1997) pointed out that the streaks can undergo an instability themselves, forming normal vortices, which can then be fed back into downstream vortices to close the loop. This self-sustaining regeneration mechanism plays a major role in the turbulence of parallel flows. The results for the transition to turbulence in viscous planar shear flows are summarized in Table 1. The flows are shear flow between parallel plates with a linear profile in the laminar case (plane Couette), pressure-driven flow between parallel plates with a parabolic profile (plane Poiseuille), and pressure-driven flow down a pipe, also with a parabolic profile (Hagen–Poiseuille). The various Reynolds numbers are defined as follows:

- Re_E *Energy stability*: as above.
- Re_G *Global stability*: up to this Reynolds number the flow is globally stable, and any perturbation will decay, perhaps after a long transient during which the energy can grow above the initial energy.
- Re_T *Reynolds number near which experiments indicate a transition to turbulence*.
- Re_L *Reynolds number for linear instability*.

For sufficiently low Re , all flows are linearly stable. For plane Couette flow and pipe flow, we know that the flows cannot be globally stable at Reynolds numbers above the given ones because of the existence of 3-dimensional stationary states or traveling waves

Flow	Re _E	Re _G	Re _T	Re _L
Plane Couette flow	20.7	125	310	∞
Plane Poiseuille flow	49.6	≈ 1000	1000	5772
Hagen–Poiseuille flow	81.5	1250	2250	∞

Table 1. Critical Reynolds numbers for parallel shear flows.

(Nagata, 1990; Ehrenstein & Koch, 1991; Clever & Busse 1997; Faisst & Eckhardt, 2003; Wedin & Kerswell, 2004). Two of the flows do not show a linear instability, and for the third one, it appears at values far above the ones where the transition to turbulence occurs. Incidentally, plane Poiseuille flow provides an example of a flow profile that is inviscidly stable by Rayleigh’s criterion but becomes unstable when viscosity is included.

In all three cases, the value for transition to turbulence is somewhat uncertain because of the absence of a sharp transition (Boberg & Brosa, 1988; Darbyshire & Mullin, 1995; Bottin et al., 1998). There is evidence that this is connected with the formation of a chaotic saddle in phase space (Schmiegel & Eckhardt, 1997). Scanning an amplitude–Reynolds number plane for perturbations in a low-dimensional model indeed shows a sensitive dependence on initial conditions and huge variations in lifetimes for neighboring trajectories (see figure in color plate section). The lifetimes of perturbations are exponentially distributed, a clear signature of a chaotic saddle.

Turbulent shear flows: The energy dissipation in a turbulent shear flow can be related to the velocity difference U and the width L of the flow as

$$\varepsilon_V = c_\varepsilon(\text{Re})U^3/L \tag{6}$$

with a dissipation factor $c_\varepsilon(\text{Re})$ that depends on the Reynolds number $\text{Re} = UL/\nu$. For laminar parallel flows, $c_\varepsilon \sim 1/\text{Re}$. For turbulent shear flows, the variational theories of Busse (1970), Doering & Constantin (1992), Kerswell (1997), and Nicodemus et al. (1997) show that in the limit of infinite Reynolds number, $c_\varepsilon(\text{Re})$ can be rigorously bounded from above. The theory bounds c_ε through a variational functional with a background profile $\phi(y)$, with the constraint that the background profile has to be energy stable. The best bound is $c_\varepsilon \leq 0.0109$. Comparing with experiment, one notes that the observed values are lower and that for smooth boundaries, they tend to decrease for increasing Reynolds number.

The presence of a large-scale shear introduces an anisotropy into the flow, which also affects the turbulent statistics. While in an isotropic turbulent flow the odd moments of the normal derivative of the downstream

component vanish, this is no longer the case in a turbulent shear flow. Dimensional estimates by Lumley (1967) suggest that the anisotropy should vanish like $1/\text{Re}$, but experimental and numerical evidence indicates that the decay is much slower. Current efforts aim at extracting information about the relevant process from the dynamics of passive scalars: the scalar fields develop characteristic ramps and cliffs that can be related to the asymmetry in the distributions of the gradients (Schumacher & Sreenivasan, 2003).

Other shear flows: In viscoelastic fluids, the interaction between shear and internal degrees of freedom can also give rise to much more complicated instabilities for which Squire’s theorem does not hold. The reduction of turbulent drag by small additions of long flexible polymers remains a fascinating phenomenon awaiting explanation (Lumley, 1969).

In astrophysics a combination of differential motion in the plasma and the presence of a magnetic field can give rise to instabilities that are responsible for the transport of angular momentum, thus solving a long-standing puzzle about the angular momentum distribution in galaxies (Balbus & Hawley, 1998).

SHOCK WAVES

In classical gas dynamics, a shock wave is a sharp, stepwise increase of density, pressure, and temperature that propagates at a supersonic speed with respect to the fluid ahead of it while remaining subsonic with respect to the fluid behind it. The fluid entropy increases after passing through the shock. Shock waves can be formed as a result of numerous processes such as supersonic motion of bodies (aircraft, meteors, bullets) in the atmosphere (see Figure 1), explosions in atmosphere and ocean, collapse of bubbles in the course of cavitation, and gas flow out of a nozzle in rockets. Also, the propagation of a nonlinear nondispersive wave (simple wave), in which each point of the profile propagates at its own velocity, generally results in the shock formation.

The changes (jumps) of different physical (thermodynamic) quantities at a shock satisfy specific relations (boundary conditions) following from the conservation of mass, momentum, and energy (mechanical plus thermodynamical). In the reference frame of the shock front, they can be presented in the form

$$[\rho v_n] = 0, \quad [p + \rho v_n^2] = 0, \quad \left[\frac{v_n^2}{2} + w \right] = 0. \quad (1)$$

Here the square brackets denote the difference of the corresponding values at the shock; v_n is fluid velocity component normal to the front; w is enthalpy; p and ρ are, respectively, pressure and density. In the reference frame in which the fluid before the shock is immovable, v_n is $-V$ where V is the shock propagation velocity.

Figure 1. Shadowgraph showing shock waves produced by a Winchester 0.308 caliber bullet traveling through air at about Mach 2.5. (With courtesy from Ruprecht Nennstiel, Wiesbaden, Germany.)

The velocity of tangential fluid motion at the shock is continuous.

Equations (1) give, in particular,

$$w_2 - w_1 = \frac{1}{2}(U_2 + U_1)(p_2 - p_1), \quad (2)$$

where $U = 1/\rho$ is the specific volume, and subscripts 1 and 2 refer to the gas in front of and behind the shock. The enthalpy w can be expressed in terms of p and ρ via the thermodynamic equation of state. As a result, if the gas parameters p_1 and U_1 before the shock are given, Equation (2) determines the dependence between p_2 and U_2 called the Hugoniot adiabat. It differs from the Poisson adiabat that relates p and ρ in a perfect gas in which entropy is constant.

In a stable shock wave the entropy increases due to dissipative processes occurring inside the shock front, which is actually a transient layer of a finite thickness that grows with viscosity and thermal conductivity in the medium. If the transition region remains thin compared with the outer motion scale, it can be considered a discontinuity at which the boundary conditions (1) (which do not depend on the specific dissipation mechanism) remain valid. Note that if only thermal conductivity determines the shock front width (i.e., viscosity is neglected), the shock front can contain a discontinuity (isothermal jump) inside it.

General relations concerning shock waves are simplified in the important case of a polytropic gas in which p is proportional to ρ^γ , where $\gamma = c_p/c_v$, and c_p and c_v are heat capacities at constant pressure and volume, respectively. For example, in a very strong shock when $p_2 \gg p_1$ and the Mach number, $M = V \cdot c \gg 1$ (c is the speed of sound), the ratios of gas densities and temperatures (T) behind and before the shock are

$$\frac{\rho_1}{\rho_2} = \frac{U_2}{U_1} = \frac{\gamma - 1}{\gamma + 1}, \quad \frac{T_2}{T_1} = \frac{\gamma - 1}{\gamma + 1} \frac{p_2}{p_1}. \quad (3)$$

Note that the maximal gas compression remains finite.

Among the dynamic problems associated with shock waves is that of shock reflection from a hard wall. If the

incidence is normal to the wall, the pressure increases to more than twice that in an incident wave (for a linear wall the pressure is doubled). If a shock of moderate strength is incident obliquely under a sufficiently large grazing angle, the shock is reflected before reaching the wall (Mach stem effect).

Another important problem is a spherical shock from an explosion. For very strong spherical waves, a self-similar solution exists, in which the shock front radius R increases as $t^{2/5}$, whereas the pressure and particle velocity decrease as R^{-3} and $R^{-3/2}$, respectively. For a curved shock front, the solution can be found by an approximation: local shock curvature at each moment is related to the rays normal to the front, and the fluid flows along these ray tubes as in channels of variable width (Whitham, 1974).

A more general description of nonstationary flows containing shocks can be achieved for one-dimensional motions such as the waves in a tube excited by a piston moving at its end. The one-dimensional equations of motion for an ideal gas can be rewritten in terms of two Riemann invariants, $J_{\pm}$:

$$\left[\frac{\partial}{\partial t} + (v \pm c) \frac{\partial}{\partial x} \right] J_{\pm} = 0, \\ J_{\pm} = v \pm \int \frac{dp}{\rho c} = v \pm \frac{2c}{\gamma - 1} \quad (4)$$

(the latter expressions are written for a polytropic gas). Here $c(\rho) = (dp/d\rho)^{1/2} = (\gamma p/\rho)^{1/2}$ is the local speed of sound. Correspondingly, there are two families of trajectories-characteristics, $dx/dt = v \pm c$ on the (x, t) plane, along which small perturbations that are linear sound waves propagate. In a particular case when one of the invariants is constant, there is a progressive simple (Riemann) wave that travels at a local velocity $v \pm c$. In such a wave, the variables are related by $v = \pm \int dp/\rho c$. Each point of the simple wave profile propagates at its own, constant velocity, and if the velocity decreases with x , at some moment the motion becomes multivalued (the wave breaks). In gas dynamics this is physically impossible, which means the formation of a shock wave at which the energy of the continuous part of the wave dissipates.

An important particular case is that of small nonlinearity when $p(\rho) \approx p_0 + c_0^2 \rho'$, where p_0 and c_0 refer to the equilibrium state (in the absence of the wave), and ρ' is density variation in the wave. This corresponds to nonlinear acoustics where the velocity of a weak shock wave is approximately the average of the linear sound speeds in front of and behind the shock. In particular, an initially sinusoidal wave transforms into a sawtooth one.

Simple waves may exist in different nondispersive, nonlinear physical systems. One example is a nonlinear surface wave in shallow water when the characteristic wavelength is much larger than the depth of the water

layer, h . Such a wave propagates at the local velocity of $c(\eta) = \sqrt{g(h + \eta)}$, where g is gravitational acceleration and $\eta(x, t)$ is the local water surface displacement with respect to its unperturbed level, h . In general, this wave breaks at a finite distance so that the long-wave approximation becomes invalid in the vicinity of the breaking point. The breaking can have different outcomes. Due to dispersion, the wave can generate oscillations that eventually become solitons, or, at larger steepness, the wave crest may break, possibly forming a turbulent front (bore), somewhat similar to a shock.

Magnetohydrodynamic Shock Waves

Shock waves can form in plasma. If the plasma is sufficiently dense, it can be treated as a compressible fluid that has electrical conductivity. When such a fluid moves in a magnetic field, the motion induces electric currents. Interaction between the currents and the magnetic field can significantly affect the fluid motion. Interaction between hydrodynamic and electromagnetic phenomena is the subject of *magnetohydrodynamics*. These phenomena are important in, for example, astrophysics, where at large-scale motions, space plasma typically behaves as a conducting fluid.

In a linear approximation, magnetohydrodynamic (MHD) waves are classified as “slow” and “fast” magnetic sound in which fluid compressibility is significant, and Alfvén waves depending only on magnetic field. In these waves magnetic perturbations are polarized perpendicular to the basic constant magnetic intensity vector $\mathbf{H}$ and group velocity is directed along $\mathbf{H}$. Finite-amplitude magnetic sound is distorted with a possible formation of MHD shocks.

As in nonmagnetic gas dynamics, parameters of MHD shock waves can be determined from boundary conditions at the discontinuity, which differ from the Rankine–Hugoniot conditions in that they include the magnetic field at both sides of the shock. The corresponding generalization of the Hugoniot adiabat reads (in the CGS system)

$$(\varepsilon_2 - \varepsilon_1) + \frac{1}{2}(p_2 + p_1)(U_2 - U_1) \\ + \frac{1}{16\pi}(U_2 - U_1)(H_{\tau 2} - H_{\tau 1})^2 = 0, \quad (5)$$

where H_{τ} is the component tangential to the shock front. In fluids with a positive thermal expansion coefficient, both pressure and density always increase at the shock, as in classical gas dynamics.

The nonshock discontinuities in MHD include tangential discontinuities, in which the vectors of fluid velocity and magnetic field are parallel to the discontinuity plane (in the comoving reference frame), and rotational (Alfvén) discontinuities in which the normal velocity component of velocity is nonzero but

continuous whereas the vector $\mathbf{H}$ rotates around the normal with constant absolute value.

In plasma, dispersion can cause an oscillating shock structure and solitary wave formation. If plasma is rarefied so that the free path of electrons exceeds the shock front thickness, the so-called noncollisional shocks may exist.

Electromagnetic Shock Waves

Another class of shock waves occurs in media that can be macroscopically immovable but have nonlinear electromagnetic parameters; for example, the dependence between the vectors of magnetic induction and the magnetic field, $\mathbf{B}(\mathbf{H})$, or between their electric counterparts, $\mathbf{D}(\mathbf{E})$, are nonlinear. If the nonlinearity is relatively strong and dispersion effects are small, electromagnetic waves can propagate as simple waves, resulting in the formation of electromagnetic shocks.

Boundary conditions at a shock can be obtained by integrating Maxwell's equations over the shock transition layer, to give

$$[\mathbf{n} \times (\mathbf{E}_2 - \mathbf{E}_1)] = \frac{U_n}{c_0} (\mathbf{B}_2 - \mathbf{B}_1), \quad (6)$$

$$[\mathbf{n} \times (\mathbf{H}_2 - \mathbf{H}_1)] = \frac{U_n}{c_0} (\mathbf{D}_2 - \mathbf{D}_1),$$

$$B_{n2} = B_{n1}, D_{n2} = D_{n1},$$

where $\mathbf{n}$ is a normal to the discontinuity surface, c_0 is the light speed in vacuum, and U_n is the normal component of shock velocity. Typically only either magnetic or electric properties of the medium are nonlinear. In the former case, an expression for the shock velocity is

$$\frac{\varepsilon U_n^2}{c^2} = \frac{H_{\tau 2} - H_{\tau 1}}{B_{\tau 2} - B_{\tau 1}}. \quad (7)$$

Electromagnetic shock waves are observed in ferrites, ferroelectrics, and semiconductors, and they have been used for construction of powerful impulse generators. In nonlinear dispersive systems, such as nonlinear transmission lines, the shock transition can be oscillating, and as dissipation approaches zero, it becomes a solitary electromagnetic wave.

SINAI–RUELLE–BOWEN MEASURES

What is a natural invariant measure? In a probabilistic approach to dynamical systems, one seeks to understand average or almost-sure behavior, particularly in the limit as time tends to infinity. In these studies, it is often fruitful to have a stationary process, or equivalently, an *invariant probability measure*. Consider a map f on a bounded domain U of a Euclidean space or a manifold with $f(U) \subset U$. (We will restrict ourselves to the discrete-time case, but the discussion is equally valid for continuous-time.) In general, f admits infinitely many mutually singular invariant probability measures, and the ergodic theory of (f, μ) depends on the choice of μ . The purpose of this entry is to discuss what constitutes a “natural” invariant measure.

Throughout this discussion, we will adopt the view that only properties that hold on positive Lebesgue measure sets are observable. A first attempt to characterize natural invariant measures is to require that they have densities. Thus for a Hamiltonian system, Liouville measure is regarded as natural. This criterion runs into difficulties with dissipative systems. Suppose that f is volume-decreasing with an attractor $\Lambda = \bigcap_{n \geq 0} f^n(U)$. Since there is no recurrence behavior on $U \setminus \Lambda$, by the Poincaré recurrence theorem, all the invariant probability measures are supported on Λ . Observe that with f decreasing volume, Λ must necessarily have Lebesgue measure zero. Thus f cannot have an invariant density.

For dissipative dynamical systems, then, we must relax the idea of a natural invariant measure from one that has a density to one that reflects the properties of positive Lebesgue measure sets. We discuss below three closely related sets of ideas that go in this direction. In less rigorous discussions, the first two are often confused, even though as we will see, they are different substantively and mathematically.

SRB Measures

Sinai–Ruelle–Bowen measures or *SRB measures* were first introduced for Anosov systems and Axiom A attractors; see Sinai (1972), Bowen (1975), and Ruelle (1978). The idea was later extended to the non-uniform hyperbolic setting (See **Horseshoes and hyperbolicity in dynamical systems**), and the name SRB measure was introduced in the review article by Eckmann–Ruelle (1985).

The idea is as follows: SRB measures live on strange attractors. The situation being chaotic, there are positive Lyapunov exponents and unstable manifolds. In the same way that the next best scenario to having a differentiable function is to have partial derivatives, if the dissipative nature of a map prevents it from having an invariant measure that is smooth, then the closest approximation would be one that is smooth in certain directions. The expanding property of a map smoothes out invariant measures along unstable manifolds.

We now give the precise definition. Consider a C^2 invertible map f and an f -invariant Borel probability measure μ . We assume that f has positive Lyapunov exponents and hence unstable manifolds μ -almost everywhere. On each k -dimensional unstable leaf γ , let m_γ denote the k -dimensional Lebesgue measure. Then we say μ is an SRB measure if the conditional measures of μ on unstable leaves have densities with respect to the measures m_γ .

The geometric definition of SRB measures given above turns out to be equivalent to the following “variational principle”: SRB measures are exactly those invariant measures for which the Kolmogorov–Sinai entropy of the system is equal to the sum of its positive Lyapunov exponents. (For other invariant measures, entropy is smaller.) If there are no zero Lyapunov exponents, there is a structure theorem that says that SRB measures have at most a countable number of ergodic components, and each ergodic component is mixing up to certain permutations (See **Horseshoes and hyperbolicity in dynamical systems**). Relations to other notions of natural invariant measures will be mentioned as we go along.

We explained earlier that SRB measures is a notion associated with strange attractors. This does not mean that every strange attractor necessarily has an SRB measure. In practice, one often assumes that it does, but mathematically, this question is far from resolved. In fact, not many attractors have been rigorously proved to have SRB measures. The main examples are Axiom A attractors and a class of attractors with one direction of instability including certain Hénon attractors (see Young, 2002).

Physical Measures

Let f be a map and μ an invariant probability measure. We say μ is a *physical measure* if there is a positive

Lebesgue measure set V in the phase space such that for every continuous observable φ , we have

$$\frac{1}{n} \sum_{i=0}^{n-1} \varphi(f^i x) \rightarrow \int \varphi d\mu$$

for every $x \in V$. Thus, physical measures are those invariant measures that can be *observed*: Suppose we pick an initial condition $x \in V$ and plot the first n points of its trajectory. The resulting picture can be seen as that of a measure giving weight $1/n$ to each one of the points $x, f(x), f^2(x), \dots, f^{n-1}(x)$. For n large, it is a good approximation of μ .

One of the reasons—some would say the main reason—why SRB measures are important is that all ergodic SRB measures with no zero Lyapunov exponents are physical measures.

Not all physical measures are SRB measures, however. For examples, point masses on attractive fixed points are physical measures. Unlike SRB measures, which are associated with chaotic behavior and have rich, well-defined structures, physical measures have no identifiable characteristics aside from the fact that they are observable.

Zero-noise Limits

If one subscribes to the view that the world is inherently noisy, then the following notion proposed by Kolmogorov is perhaps the most relevant notion of observability. Let f be a map on a bounded domain, and let $P^\varepsilon(\cdot|\cdot)$, $\varepsilon > 0$ be a family of Markov chains representing random perturbations of f ; that is, the transition probabilities $P^\varepsilon(\cdot|x)$ have the following interpretation: instead of jumping from x to $f(x)$, $P^\varepsilon(\cdot|x)$ gives the distribution of possible images starting from x . We may think of it as the uniform distribution on an ε -disk centered at $f(x)$ or a Gaussian with ε variance. Let μ_ε be the marginal of the stationary measure of the process defined by $P^\varepsilon(\cdot|\cdot)$, and let $\varepsilon \rightarrow 0$. Limit points of μ_ε are called *zero-noise limits*.

Unlike SRB measures or physical measures, the existence of which leads to unresolved questions, systems defined on compact regions always have zero-noise limits. It is hoped that in most situations, they coincide with the other notions of natural invariant measures. This has been proved for Axiom A attractors and a handful of other examples.

SINE-GORDON EQUATION

In normalized units, the classical sine-Gordon (SG) equation is the nonlinear partial differential equation

$$\frac{\partial^2 \phi}{\partial x^2} - \frac{\partial^2 \phi}{\partial t^2} = \sin \phi, \quad (1)$$

where $\phi(x, t)$ is a field in two dimensions—space and time. Since its introduction in 1939 by Yakov Frenkel and Tatiana Kontorova as a model for the dynamics of crystal dislocations (Frenkel & Kontorova, 1939), this equation has found a variety of applications, including Bloch wall dynamics in ferromagnetics and ferroelectrics, fluxon propagation in long Josephson (superconducting) junctions, self-induced transparency in nonlinear optics, spin waves in the A-phase of liquid ^3He at temperatures near to 2.6 mK, and a simple, one-dimensional model for elementary particles (Bullough, 1977; Scott, 2003). The name stems from the linear Klein–Gordon equation $\partial^2 \phi / \partial x^2 - \partial^2 \phi / \partial t^2 = \phi$, where the “joke” may be due to Martin Kruskal or it may not (Bullough & Caudrey, 1980).

The SG equation can be physically modeled as a linear array of weakly coupled pendula, suggesting traveling-wave solutions of the form

$$\phi = 4 \arctan \exp \left\{ \pm (x - vt) / \sqrt{1 - v^2} \right\} \quad (2)$$

with $v < 1$. These solutions are called a kink and an antikink, respectively, since at $x = -\infty, \phi \rightarrow 0$, and at $x = +\infty, \phi \rightarrow 2\pi$ for the $+$ sign, while at $x = -\infty, \phi \rightarrow 2\pi$ and at $x = +\infty, \phi \rightarrow 0$ for the $-$ sign. In the context of the physical model, ϕ twists from 0 to 2π for the kink and untwists from 2π to 0 for the antikink. Alternatively $\phi / 2\pi$ has “topological charge” $+1$ for each kink and -1 for each antikink. Each of these is a one-soliton solution, but there are also N -soliton solutions for the boundary conditions $\phi \rightarrow 0 \pmod{2\pi}$ as $x \rightarrow \pm\infty$. (In “light-cone coordinates” (see below) the N -soliton solutions were given by Caudrey et al. (1973); see the detailed history in Bullough & Caudrey (1980)).

Figure 1. A kink-kink solution of the SG equation plotted from Equation (3) with $v = 0.5$.

Figure 2. A kink-antikink solution of the SG equation plotted from Equation (4) with $v = 0.5$.

The simplest 2-soliton solution of SG Equation (1) is the kink-kink collision given by Perring & Skyrme (1962) as

$$\phi(x, t) = 4 \arctan \left[\frac{v \sinh(x/\sqrt{1-v^2})}{\cosh(vt/\sqrt{1-v^2})} \right] \quad (3)$$

as shown in Figure 1 for $v = 0.5$. Similarly, Figure 2 shows a kink-antikink collision, which is plotted from

$$\phi(x, t) = 4 \arctan \left[\frac{\sinh(vt/\sqrt{1-v^2})}{v \cosh(x/\sqrt{1-v^2})} \right] \quad (4)$$

also with $v = 0.5$.

The kink-antikink equation takes an interesting form if the velocity parameter (v) is allowed to be imaginary. For example, setting

$$v = i\omega/\sqrt{1-\omega^2}, \quad \omega < 1,$$

Equation (4) becomes the stationary breather (or “bion”)

$$\phi(x, t) = 4 \arctan \left[\left(\frac{\sqrt{1-\omega^2}}{\omega} \right) \frac{\sin \omega t}{\cosh \sqrt{1-\omega^2} x} \right], \quad (5)$$

Figure 3. A stationary breather plotted from Equation (5) with $\omega = \pi/5$.

a localized, oscillating solution that is plotted in Figure 3 for $\omega = \pi/5$. Because Equation (1) is invariant under the Lorentz transformation

$$x' = (x - vt) / \sqrt{1 - v^2}$$

and

$$t' = (t - xv) / \sqrt{1 - v^2}, \quad (6)$$

this stationary breather can be boosted into a moving frame. Thus,

$$\phi(x, t) = 4 \arctan \left\{ \frac{\sqrt{1 - \omega^2}}{\omega} \sin \left[\frac{\omega(t - v_c x)}{\sqrt{1 - v_c^2}} \right] \times \operatorname{sech} \left[\frac{\sqrt{1 - \omega^2}(x - v_c t)}{\sqrt{1 - v_c^2}} \right] \right\}$$

is an exact solution of the SG equation moving with an envelope velocity (v_c) that is equal to the reciprocal of its carrier velocity $v_c = 1/v_e$.

Because $\phi(x, t)$ is defined for each value of x , the Hamiltonian description is infinite dimensional. A standard form of the Hamiltonian (or energy) is (Bullough & Timonen, 1995)

$$H = \int \left[\frac{1}{2} \Pi^2(x, t) + \frac{1}{2} (\partial \phi / \partial x)^2 + (1 - \cos \phi) \right] dx. \quad (7)$$

Hamilton's equations then take the form

$$\frac{\delta H}{\delta \phi} = -\dot{\Pi} \quad \text{and} \quad \frac{\delta H}{\delta \Pi} = \dot{\phi}, \quad (8)$$

where the δ s indicate functional (or Frechét) derivatives. The second of Equations (8) yields $\dot{\phi} = \Pi$ and the first yields $-\dot{\phi} = -\dot{\Pi} = -\phi_{xx} + \sin \phi$, which is the SG equation. Computing H in the rest frame, one finds rest masses equal to 8 for both kinks and antikinks, while for stationary breathers the rest masses are $16\sqrt{1 - \omega^2}$. Evidently, a stationary breather is a bound pair of a kink and an antikink oscillating at frequency ω .

The SG equation is a completely integrable Hamiltonian system, which means that the number of independent constants of motion is equal to the number of degrees of freedom (Liouville's theorem). As the number of degrees of freedom is infinite (through the labels x), the theorem is not obvious, but an infinite number of commuting and independent constant action variables can be found. Equivalently, solutions of the SG equation can be obtained through a Bäcklund transformation (BT) or by using an inverse scattering method (ISM).

In BT and ISM studies, it is convenient to transform the independent variables as

$$x \rightarrow \xi = (x + t)/2 \quad \text{and} \quad t \rightarrow \tau = (x - t)/2,$$

whereupon Equation (1) becomes

$$\frac{\partial^2 \phi}{\partial \xi \partial \tau} = \sin \phi. \quad (9)$$

These new variables (ξ and τ) are sometimes called "light-cone" coordinates because they point in the directions of characteristics in the (x, t) -plane.

The SG equation first appeared in light-cone coordinates in the mathematical study of surfaces of constant negative Gaussian curvature by Albert Bäcklund (Lamb, 1976). In 1883, he discovered the first BT, which can be written as

$$\begin{aligned} \phi'_x &= \phi_x + 2k \sin(\phi + \phi')/2, \\ \phi'_t &= -\phi_t + 2k^{-1} \sin(\phi - \phi')/2 \end{aligned} \quad (10)$$

for any real value of the parameter k . The integrability condition $\phi'_{xt} = \phi'_{tx}$ implies both $\phi_{xt} = \sin \phi$ and $\phi'_{xt} = \sin \phi'$; thus, Equations (10) transform a known solution ϕ of the SG in light-cone coordinates to a second solution ϕ' . As $\phi = 0$ is a solution, the single-kink solution is found to be $\phi' = 4 \arctan \exp(kx - k^{-1}t)$ for this real value of k .

Bullough (1980), for example, shows how the BT Equation (10) becomes the Lax pair for an ISM analysis first written down by Ablowitz et al. (1973) (AKNS). Independently, Takhtajan & Faddeev (1974) gave the corresponding expressions for the covariant SG Equation (1). AKNS's Lax pair is

$$\frac{\partial}{\partial \xi} \begin{bmatrix} \psi_1 \\ \psi_2 \end{bmatrix} = \begin{bmatrix} -i\lambda & -\phi_\xi/2 \\ \phi_\xi/2 & i\lambda \end{bmatrix} \begin{bmatrix} \psi_1 \\ \psi_2 \end{bmatrix},$$

where ψ_1 and ψ_2 are components of the scattering solution and λ is a complex scattering parameter together with the τ -dependence

$$\frac{\partial}{\partial \tau} \begin{bmatrix} \psi_1 \\ \psi_2 \end{bmatrix} = \frac{i}{4\lambda} \begin{bmatrix} \cos \phi & \sin \phi \\ \sin \phi & -\cos \phi \end{bmatrix} \begin{bmatrix} \psi_1 \\ \psi_2 \end{bmatrix}. \quad (11)$$

It is readily checked that the cross-derivative condition

$$\frac{\partial}{\partial \tau} \frac{\partial}{\partial \xi} \begin{bmatrix} \psi_1 \\ \psi_2 \end{bmatrix} = \frac{\partial}{\partial \xi} \frac{\partial}{\partial \tau} \begin{bmatrix} \psi_1 \\ \psi_2 \end{bmatrix}$$

implies Equation (9), thus providing the basis for an ISM analysis.

Assuming that $\phi \rightarrow 0 \pmod{2\pi}$ as $\xi \rightarrow \pm\infty$, the time evolution matrix defined in Equation (11) takes the simple asymptotic form

$$\frac{i}{4\lambda} \begin{bmatrix} 1 & 0 \\ 0 & -1 \end{bmatrix};$$

thus the reflection coefficient and the residues r_n of its upper-half-plane-poles (in the λ plane) evolve with time as

$$b(\lambda, \tau) = b(\lambda, 0)e^{-i\tau/2\lambda}, \\ r_n(\tau) = r_n(0)e^{-i\tau/2\lambda_n},$$

where $b(\lambda, \tau)$ is the reflection coefficient of the solution and n is an index that runs over the number (N) of soliton components.

The evolved solution of Equation (9) turns out to be

$$\frac{\partial\phi}{\partial\xi}(\xi, \tau) = 4K(\xi, \xi; \tau), \quad (12)$$

where $K(\xi, z; \tau)$ is a solution of the (Gel'fand-Levitan-Marchenko) integral equation

$$K(\xi, z; \tau) = B^*(\xi + z; \tau) - \int_{\xi}^{\infty} \int_{\xi}^{\infty} K(\xi, y; \tau) B(y + y'; \tau) \times B^*(z + y'; \tau) dy dy' \quad (13)$$

with $z > \xi$, and

$$B(\xi + z; \tau) \equiv \frac{1}{2\pi} \int_{-\infty}^{\infty} b(\lambda, 0) e^{i\lambda(\xi+z) - i\tau/2\lambda} d\lambda - i \sum_{n=1}^N r_n(0) e^{i\lambda_n(\xi+z) - i\tau/2\lambda_n} \quad (14)$$

is determined from a scattering analysis of the initial conditions.

The simplest example of this ISM formulation is obtained by assuming that the initial potential is reflectionless ($b(\lambda, \tau) = 0$) and has but one bound state ($N = 1$), corresponding to a single pole at ($\lambda_1 = i\kappa$) on the imaginary axis of the upper half λ -plane with residue $r_1 = \pm 2i\kappa$. Thus, from Equation (14)

$$B(\xi + z; \tau) = \pm 2\kappa e^{-\kappa(\xi+z) - \tau/2\kappa},$$

so Equation (13) takes the form

$$K(\xi, z; \tau) = \pm 2\kappa e^{-\kappa(\xi+z) - \tau/2\kappa} - 4\kappa^2 e^{-\tau/\kappa} \int_{\xi}^{\infty} \int_{\xi}^{\infty} K(\xi, y; \tau) e^{-\kappa(y+y')} \times e^{-\kappa(z+y')} dy dy'.$$

As $K(\xi, z; \tau) \propto \exp(-\kappa z)$, this integral equation is solved for

$$K(\xi, z; \tau) = \pm \frac{2\kappa \exp[-\kappa(\xi + z) - \tau/2\kappa]}{1 + \exp(-4\kappa\xi - \tau/\kappa)}.$$

Thus, from Equation (12)

$$\frac{\partial\phi}{\partial\xi} = \pm 4K(\xi, \xi; \tau) = \pm 4\kappa \operatorname{sech}(2\kappa\xi + \tau/2\kappa),$$

which integrates to

$$\phi(\xi, \tau) = 4 \arctan\{\exp[\pm(2\kappa\xi + \tau/2\kappa)]\}.$$

Finally, one can transform back to the laboratory (x, t) coordinates, whereupon the corresponding solution of Equation (1) is the kink or antikink of Equation (2) with its laboratory velocity identified as

$$v = \frac{1 - 4\kappa^2}{1 + 4\kappa^2} = \frac{1 + 4\lambda_1^2}{1 - 4\lambda_1^2}. \quad (15)$$

With an appropriate choice of the constants c_1 and c_2 , the kink-antikink solution of Equation (4) can be generated in a similar manner from the assumption that

$$B(\xi + z; 0) = c_1 e^{-\kappa_1(\xi+z)} + c_2 e^{-\kappa_2(\xi+z)}, \quad (16)$$

where

$$\kappa_1 = \frac{1}{2} \sqrt{\frac{1+v}{1-v}} \quad \text{and} \quad \kappa_2 = \frac{1}{2} \sqrt{\frac{1-v}{1+v}}.$$

These integrable properties of the SG equation are shared by the sinh-Gordon equation and the Liouville equation for which the sine function in Equation (1) is replaced by a hyperbolic-sine function and by an exponential function, respectively—although the Liouville equation has no inverse scattering solution. Perhaps the most striking property of SG solitons, however, is their topological stability, which is evidenced by their nonzero rest masses. This property is carried into three space dimensions by the theory of skyrmions.

Equation (1) can be embedded in a more general framework of inverse-scattering methods, with the Hamiltonian expressed in terms of finite numbers of kinks, antikinks, and breathers, in addition to a continuous spectrum of radiation (Bullough, 1980). In the mid-1970s, Roger Dashen, Brosi Hasslacher, and Andre Neveu used semiclassical quantum methods to study this system, finding the mass (or energy) spectrum of the breather of Equation (5) to be

$$M_n = 16 \sin\left(\frac{n}{16}\right),$$

where n is a positive integer less than 8π (Dashen et al., 1975). They correctly conjectured this "DHN spectrum" to be exact—a result of theoretical significance

because it shows that semiclassical analyses of nonlinear field theories can provide useful information about exact mass spectra.

The statistical mechanics of the SG equation is carried out in both the quantum and classical cases in Bullough & Timonen (1995), with a further appraisal of the action-angle variables in one space dimension. Bullough (1977) develops the theory of double and multiple SG equations (with $\sin \phi$ in Equation (1) replaced by $\pm[\sin \phi + (\sin \phi / 2) / 2]$, $\sin \phi + (\sin \phi / 3) / 3 + 2(\sin 2\phi / 3) / 3$, etc.) in connection with models for degenerate self-induced transparency of metal vapors and of spin waves of the B-phase of liquid ^3He near 2.6 mK.

SINGULARITY THEORY

Does the view from your window encompass a range of hills or mountains? If you are so blessed, you will see immediately both of the persistent singularities that can be observed generically; they are indicated on the mountains sketched in Figure 1, a section of a remote but important range called the Transversal Alps. The points marked “country” are known as fold singularities. Actually the outline of the mountains, which in reality is a mapping of a surface contour onto the retina of the eye, is composed of an infinite number of fold singularities. The two points marked “western” are known as cusp singularities. They occur where a line of folds along the edge of a mountain meets another line of folds along the gully between the mountains.

If the view from your office is more urban in character—of faces in the street, say—you will probably see many more of these two fundamental singularities. You must search a lot harder to find other types of singularities, or purposefully create one, because all other singularities dissolve under the slightest perturbation into either a fold or a cusp. This remarkable fact was first proved by Whitney (1955) whose fundamental discoveries about singularities of differentiable mappings were developed into catastrophe theory and toolkits for treating bifurcation problems with parameters, by mathematicians such as Mather (in a series of very technical papers from 1968 to 1971), Thom (1972), Martinet (1982), Arnol'd et al. (1985), and Golubitsky & Schaeffer (1985).

Singularity theory is not secret mathematicians' business though, and a more apt name for the whole business would be “theory and applications of

Figure 1. The Transversal Alps.

singularities.” It is one of the more accessible entry points both to highly abstract areas of mathematics and to applied fields such as dynamical systems and bifurcations, because singularities can arise in almost any problem. The prerequisites are standard fare in first- and second-year mathematics courses: knowledge of Taylor’s formula, the implicit function theorem, the theorem of existence and uniqueness, and some basic group theory, and willingness to learn some terminology.

Naturally, we should begin with a definition of singularity; (after Lu, 1976): Let f be a differentiable mapping from $\mathcal{M}$ to $\mathcal{N}$, where $\mathcal{M}$ and $\mathcal{N}$ are differentiable manifolds. A point $x_0 \in \mathcal{M}$ is a singular point of f if $\text{rank } df(x_0) < \min \{\dim \mathcal{M}, \dim \mathcal{N}\}$, where $df(x_0)$ is the Jacobian matrix of f at x_0 . Otherwise x_0 is a regular point of f .

Singularity theory solves three key related problems: Given a mapping f , (i) it determines what types of singularities any good approximation $\tilde{f}$ to f must have; (ii) it tells us how can we perturb f slightly to obtain a nicer and simpler, but in some sense equivalent, mapping; and (iii) it provides a taxonomy of singular objects and a binary key to identify them; hence, it is a *classification science*.

At the heart of singularity theory is a concept that is profound and yet somehow ingenuous; it is the concept of transversality. The naive (but not impercipient) version says that two curves intersect transversally if a small deformation of either one would not change the type of intersection. It is transversality that allows us to boil things down to classified normal forms.

Example 1: The mapping f from $\mathbb{R}^2$ into $\mathbb{R}^2$

$$u = x^2, \quad v = y \tag{1}$$

has a fold along $x = 0$ in the xy plane, the set of singular points is $\{(x, y) \in \mathbb{R}^2 \mid y = 2x\}$. Points along the fold remain fixed as y changes, that is, under perturbation. Equations (1) are called the *normal form* for a fold.

Example 2: The equations

$$u = xy - x^3, \quad v = y \tag{2}$$

define a mapping g from $\mathbb{R}^2$ into $\mathbb{R}^2$ for which the set of singular points is $\{(x, y) \in \mathbb{R}^2 \mid y = 3x^2\}$. The arms of the parabola are two lines of folds that come together and disappear at the cusp $(0, 0)$. Equations (2) are the normal form for the cusp, and Whitney proved that any

Figure 2. Slices through the cusp manifold (top) yield the three possible bifurcation diagrams (bottom).

Figure 3. An orthogonal path through that cusp opens into a manifold around the pitchfork.

other mapping containing a regular point satisfying the conditions

$$\begin{aligned} u_x = u_y = v_x = 0, \quad v_y = 1, u_{xx} = 0, \\ u_{xy} \neq 0, u_{xxx} - 3u_{xy}v_{xx} \neq 0 \end{aligned} \tag{3}$$

can be transformed by coordinate changes into the normal form (2). In catastrophe theory this normal form becomes the *universal unfolding* $G(x, y, u)$ of the germ $g(x) = x^3$:

$$G(x, y, u) \equiv x^3 - yx + u, \tag{4}$$

where G is the gradient of a governing potential V . One may understand the cusp by studying the surface $G(x, y, u) = 0$ shown in Figure 2. By taking slices of this surface at constant y we recover the three qualitatively different bifurcation diagrams, as shown. Now visualize a *projection* of this surface onto the (u, y) plane. We find that the two lines of folds meet at a cusp singularity, the very same that we saw in the Transversal Alps in Figure 1.

An instructive and fascinating lesson on the properties and classification of simple singularities is

to parameterize the surface $G(x, y, u) = 0$ differently. In a study of singular surfaces by Ball (2001), it was observed that although the cusp is generic in the sense that all other singularities may be perturbed to either a fold or a cusp, the surface in Figure 2 is not a unique manifold of the cusp. Because all paths through the unfolding (4) are equally valid, we may choose a path in the (x, y) plane. Any such path unfurls laterally into the u -dimension to form a different surface. It is shown from two points of view in Figure 3. Constant- u slices show up the *pitchfork* singularity (center bifurcation diagram) and two of its perturbations. From this point of view Equation (4) is a *partial* unfolding of the pitchfork (but it is not a universal unfolding of the pitchfork).

In applications, the singularity theory approach has been most successful in qualitative studies of the equilibria of dynamical systems dependent on parameters. Given a dynamical system that can be reduced to a set of ordinary differential equations (by a procedure such as Lyapunov–Schmidt reduction), a general approach is to apply defining algebraic criteria systematically to the equilibria until one discovers the highest-order or most degenerate singularity, defined by its normal form. (The binary key given in Golubitsky & Schaeffer (1985, p. 201) is extremely useful for this task.) From a universal unfolding of this *organizing center*, one can “read off” all of the possible qualitatively different bifurcation behavior of the equilibria. A great many dynamical models of physical systems have been given the singularity theory treatment, often yielding results having important implications for the prediction and control of such systems. For a few but varied examples see Ball (1999) (chemical reactions), Ball et al. (2002) (plasma physics), and Broer et al. (2003) (periodic dynamics).

SKYRMIONS

As described by quantum field theories, elementary particles are associated with the quantization of small fluctuations around the vacuum and have masses that are proportional to Planck's constant, $\hbar$; thus, in the classical limit ($\hbar \rightarrow 0$), the mass goes to zero. The properties of a particle follow from the linearization of the field equations and any nonlinear terms are responsible for the interactions between particles, which are often treated perturbatively in the coupling constants. However, the 1960s saw the emergence of a new approach to quantum field theory in which the fully nonlinear classical field equations were investigated. It was found that for certain theories, the classical nonlinear field equations had static solutions that were particle-like, in the sense that they described stable, localized, finite energy field configurations. To describe elementary particles, the field theory must be Lorentz invariant, so such a static solution can simply be Lorentz boosted to describe a particle in uniform motion. These solutions, which are known as topological solitons (or sometimes just solitons for short, though they should not be confused with the solitons of integrable systems), have some novel features in comparison with elementary particles. Because they are classical solutions, then the mass of a soliton, which is identified with the energy of the static solution, is nonzero even in the limit $\hbar = 0$. Also, because the soliton is a solution of the full nonlinear field equation, it is automatically treated nonperturbatively in the coupling constants of the theory. Quantum corrections to the classical properties of a soliton can be addressed, mainly using semiclassical methods, but the important point is that these corrections are often small, so that the classical nonlinear equations largely determine the properties of a soliton. Despite the obvious differences between elementary particles and solitons, impressive research

during the last decade has revealed a great deal of evidence for a remarkable connection between these two kinds of particles, with solitons in some weakly coupled theories appearing to be dual to elementary particles in strongly coupled theories (Olive, 1996). These developments have led to a renewed interest in solitons in field theory, particularly in supersymmetric theories.

As the name suggests, topological solitons arise in theories where there is a topological classification of field configurations, with the soliton being in a different topological sector to the vacuum and, hence, preventing its decay, since time evolution cannot change the conserved topological charge. This is perhaps most easily explained using a simple example. As a toy model we shall consider the static sine-Gordon theory in one space dimension, although our presentation will be slightly unusual in order to make the extension to three spatial dimensions a little more transparent. Consider a two-component unit vector $\phi(x) = (\phi_1, \phi_2)$, so that ϕ lies on the circle $\phi \cdot \phi = 1$. If we restrict to static fields, then the sine-Gordon model can be defined by the energy expression

$$E = \int_{-\infty}^{\infty} \left(\frac{1}{2} \frac{d\phi}{dx} \cdot \frac{d\phi}{dx} + 1 - \phi_2 \right) dx. \quad (1)$$

For finite energy the boundary condition is clearly that the field must take the constant vacuum value $\phi = (0, 1)$ at spatial infinity. The fact that the field ϕ takes the same value at the two points at spatial infinity implies a compactification of space from $\mathbb{R}$ to S^1 , arising from the identification of the points $x = -\infty$ and $x = +\infty$. Therefore, ϕ is a map $\phi: S^1 \mapsto S^1$, where the domain is compactified space and the target circle is the set of two-component unit vectors. Such maps have an associated degree, or winding number, N , due to the homotopy group relation $\pi_1(S^1) = \mathbb{Z}$. This integer-valued winding number is simply the number of times (counted with orientation) that the field winds around the target space circle as x ranges over the circle obtained from the compactification of space. The vacuum solution, with energy $E = 0$, is given by $\phi(x) = (0, 1)$ and clearly has $N = 0$. The soliton is the minimal energy field configuration in the $N = 1$ sector and has the explicit expression

$$\phi = (\sin \psi, \cos \psi) \quad \text{with} \quad \psi = 4 \tan^{-1} e^{x-a}, \quad (2)$$

where a is an arbitrary real constant. The soliton has energy $E = 8$ and the energy density (the integrand in Equation (1)) is a localized lump centered around the point $x = a$, which is the position of the soliton. The full time-dependent sine-Gordon theory follows from the Lorentz invariant Lagrangian associated with the energy (1). The static soliton solution (2) can be Lorentz boosted to provide a moving soliton solution (with any speed less than the speed of light) of the full second-order time-dependent field equations. The

antisoliton solution, with $N = -1$, is simply obtained from the soliton solution by making the replacement $(\phi_1, \phi_2) \mapsto (-\phi_1, \phi_2)$. There are no static multisoliton solutions, that is, with $N > 1$, but time-dependent multisoliton solutions can be found in closed form and describe the elastic scattering of several individual solitons (Drazin, 1983). This remarkable fact follows from the integrability property of the time-dependent sine-Gordon equation, a feature which is not shared by more realistic theories with topological solitons in three space dimensions.

The most important aspect of the sine-Gordon model on the line is the topological classification of finite energy field configurations, which follows from the homotopy group relation $\pi_1(S^1) = \mathbb{Z}$. This is the first property that needs to be generalized when searching for a three-dimensional theory with topological solitons. If we consider a theory for which finite energy implies that the field must be constant at spatial infinity, then Euclidean space $\mathbb{R}^3$ becomes compactified to the three-sphere S^3 . This is the analogue of the compactification of the line to the circle described above, and hence, we see that the simplest way to obtain a model with topological solitons is to also make the target space S^3 . Then the homotopy group relation $\pi_3(S^3) = \mathbb{Z}$ ensures that there is again an integer-valued topological charge, N , which divides finite energy field configurations into distinct topological sectors. To achieve the target space S^3 , the field can be taken to be a four-component unit vector, although an equivalent formulation is to take the field to be an $SU(2)$ -valued matrix, since S^3 is also the manifold of the group $SU(2)$. The Skyrme model (Skyrme, 1961) is such a theory and has the static energy

$$E = \int \left\{ \text{Tr}(\partial_i U \partial_i U^{-1}) - \frac{1}{8} \text{Tr}([(\partial_i U) U^{-1}, (\partial_j U) U^{-1}]^2) \right\} d^3x, \quad (3)$$

where $U(\mathbf{x}) \in SU(2)$ is the field of the model and $\partial_i = \partial/\partial x_i$ with x_i ($i = 1, 2, 3$) is the Cartesian coordinates in Euclidean space, and we have adopted the Einstein summation convention where repeated indices are summed over. Also, the square brackets denote the commutator, $[A, B] = AB - BA$. The first term in (3), called the sigma model energy by physicists and the harmonic map energy by mathematicians, is the higher-dimensional analog of the simple gradient energy given by the first term in (1) for the toy model. In order to provide a finite nonzero scale size for the soliton, the sigma model energy needs to be balanced against an additional term with an appropriate scaling behavior under spatial dilations, as required by the Derrick-Hobart theorem. In one spatial dimension, this requires a term which contains

Figure 1. Skyrmions with N from 7 to 22.

no spatial derivatives of the field, such as the final term in (1), but in three spatial dimensions, the appropriate term must be at least fourth-order in the spatial derivatives. The final term in (3), known as the Skyrme term, is the unique order-four expression whose relativistic extension provides a Lagrangian in $(3+1)$ -dimensions, which yields a nonlinear field equation that is only second order in time derivatives. The Skyrme model has a stable topological soliton, the solution with minimal energy in the $N=1$ sector, and this is known as a skyrmion. The solution is spherically symmetric but cannot be written in closed form and is only known numerically. Unlike the sine-Gordon toy model, the Skyrme model has static stable bound-state multi-solitons for all $N > 0$. These multi-skyrmions are not spherically symmetric but often have surprising discrete symmetries, including the symmetries of the Platonic solids (Battye & Sutcliffe, 2002). Figure 1 displays skyrmions with $7 \leq N \leq 22$ by plotting surfaces around which the topological charge density is concentrated.

The Skyrme model was originally introduced (Skyrme, 1961) in the early 1960s as a model for the strong interactions of hadrons. It is a nonlinear theory of pions, with the pion particles being described in the usual quantum field theory approach by the quantization of the three degrees of freedom associated with the small fluctuations of the field around the vacuum, where U is the identity matrix, with $N=0$. Skyrme identified the conserved topological charge N with baryon number and, hence, within the nonlinear pion theory baryons appear for free as the classical soliton solutions. The Skyrme model was set aside after the advent of quantum chromodynamics (QCD), but much later it was revived by Witten (1983), who

showed that it could arise from QCD as a low energy effective description in the limit in which the number of quark colors is large. Semiclassical quantization of the $N=1$ skyrmion reproduces the properties of the nucleon to within an accuracy of around 30% (Adkins et al., 1983), which is quite an achievement. There has been considerable recent progress in computing classical multi-skyrmion solutions, but it still remains to be seen whether their quantization provides a good description of nuclei.

Finally, it should be noted that in Yang–Mills–Higgs gauge theories the topological classification of field configurations arises in a slightly different way than described above for skyrmions and other modified sigma models. In gauged theories, the Higgs field is not required to be constant at infinity, and indeed, it is a nontrivial winding at infinity that provides the topological charge. In two spatial dimensions this yields vortices, and in three-dimensional space it leads to magnetic monopoles. When the Higgs field is massless, which is the situation that arises in interesting supersymmetric theories with monopoles, then the classical field equations have a particularly rich mathematical structure, and many exact results on monopole solutions are known (for a review see, e.g., Sutcliffe, 1997).

SOLAR SYSTEM

The solar system shows a multitude of periodic phenomena: from the daily rotations of the Earth, to the monthly phases of the Moon, the seasonal changes during the course of a year, the phases of Venus and other planets, the regular recurrences of comets such as Halley's (every 76 years), the 25,700 year precession of the Earth's rotation axis, all the way up to changes in the parameters of the Earth's orbit, with periods of 40,000 years and more. Closer inspection reveals small modulations on top of these periods, but it is tempting to describe these by additional periods, as in the Ptolemaic theory of cycles, epicycles, and equants. However, the dynamics of the planets is governed by gravitational forces that vary as the inverse square of the distance and, hence, are strongly nonlinear. The question arises whether this nonlinearity results in some chaos.

Johannes Kepler concluded in the early 17th century that an isolated planet would move along a Kepler ellipse (such that a line joining the planet to the Sun sweeps out equal areas in equal times). For several planets their mutual perturbations leads to perihelion precessions and other variations of orbital parameters. Taking such perturbations into account was a major issue in solar mechanics in the following centuries and led to remarkable achievements. For instance, observations of the orbit of Uranus (discovered in 1781 by William Herschel) revealed significant differences to the orbit calculated in the presence of the known planets. When interpreted as due to the influence of another planet, the position of the missing planet could be predicted, and soon thereafter the efforts of Urbain V. LeVerrier, James C. Adams, and Johannes

G. Galle were rewarded with the discovery of Neptune in 1846.

These results were obtained using perturbation theory. But does it actually converge? Advances in analytical mechanics in the 19th century suggested that an answer could be found and Gösta Mittag-Leffler included the issue of the stability of the solar system among the list of problems for a prize to be awarded in 1889 by King Oskar II of Sweden and Norway. Henri Poincaré was awarded the prize for his announcement that he could prove convergence, but in the course of revising his paper he noticed that there was a gap in the proof which he could not patch up. Instead, he discovered the intricate motions near a weakly perturbed hyperbolic fixed point, the so-called hyperbolic tangle, which effectively prevents quantitative continuation of trajectories that pass near a hyperbolic fixed point. Barrow-Green (1996) and Diau & Holmes (1996) give vivid accounts of the events surrounding the prize.

A practical answer to the question of the stability of the solar system emerged in the late 20th century with the advent of powerful computers that allow integration of the equations of motions for several million years. It was then discovered that the inner planets are most susceptible to chaos, and that the Lyapunov time (inverse of the Lyapunov exponent) is about 5 million years. To illustrate the consequences of that, we quote from Laskar (1995):

A 15 m uncertainty in the position of the Earth will grow to about 150 m in a time of 10 million years. But it will increase to 150 million km or the mean distance of Earth from the Sun within 100 million years.

As a consequence, we have difficulty predicting the Earth's orbit for times much larger than a few tens of millions of years. The consequences such an uncertainty can have are illustrated by numerical simulations for Mercury: by suitably selecting continuations, it is argued in Laskar (1995) that over a time of about 10^9 years the orbit of Mercury could change so that the planet collides with Venus and/or escapes from the solar system. It should be noted that this trajectory was especially tailored in order to show that escape is possible in principle; it does not give a clue as to how likely such an event may be.

The issue of the orbital parameters of the Earth is interesting because variations in the major rotation axis and the distance to the Sun influence our climate. In 1920, Milutin Milankovich calculated insolation data (incident solar radiation) for the Earth for long-term variations in the Earth's orbit and suggested some relationship to the appearance of past ice ages. The uncertainty in orbital parameters over periods of more than 40 million years thus indicate that reconstructing paleoclimates will be problematic (Laskar, 1999).

Besides planets there are many other objects in the solar system. Direct evidence for a chaotic trajectory has been found, for example, for the tumbling motion of Phobos and Deimos (moons of Mars) and for Saturn's moon Hyperion (Wisdom, 1987). Similarly, efforts to retrace the trajectory of Halley's comet back to its earliest recorded sighting in 163 BC gave wildly diverging results. As explained by Chirikov and Vechevslavov (1989), the orbit of Halley is chaotic with an inverse Lyapunov time of about 29 returns, so that the earliest observation is just beyond predictability. The distribution of asteroids between Mars and Jupiter shows conspicuous gaps (named after the astronomer Daniel Kirkwood) near orbits with rotation periods rationally related to the 11.9 year period of Jupiter. Such resonant interactions have strong effects on the orbits and can easily lead to collisions and escape from the resonance (Laskar, 1995; Wisdom, 1987).

The relation between the Moon, the Earth, and the Sun also holds surprises. The history of the problem, and the contributions of Babylonian, Greek, and modern astronomers to the observations and mathematical tools, is reviewed in Gutzwiller (1998). Gutzwiller also gives a quantitative example for the significance of small denominators: in order to calculate the distance between the Earth and Moon with the accuracy of 10^{-10} achievable within the Lunar Laser Ranging project, amplitudes as small as 10^{-17} have to be kept because of a significant resonance. While this does not result in positive Lyapunov exponents, it is a precursor to it, a mild form of chaos, as Gutzwiller calls it.

More surprisingly, the presence of the Moon is very important for the stability of the rotation axis of Earth: with the Moon the obliquity stays within about $\pm 1.3^\circ$ of 23.3° . Without it, the obliquity ends up in a resonance and can become as large as 60° to 90° , with catastrophic consequences for our climate and the evolution of life (Laskar et al., 1993).

Finally, it is worthwhile to point out that the presence of hyperbolic orbits in the solar system was used in connection with the satellite GENESIS (launched in August 2001) to bring it along a stable orbit close to a Lagrange point, where it will remain for a few years to collect particles in the solar wind, before being brought back to Earth along an unstable manifold (Koon et al., 2000). Exploiting trajectories that exist in the dynamical system allows the mission to be completed with minimal requirements on fuel. This mission may thus also be considered an example of chaos control, where similar ideas are being investigated.

SOLITON WAVE PACKET

See **Quantum nonlinearity**

SOLITONS

A *soliton* is a localized nonlinear wave that maintains its shape and speed as it travels, even through interaction with other waves. Another name for a localized traveling wave is a *solitary wave*. The term *soliton* was coined (by Zabusky & Kruskal, 1965) to reflect both the solitary-wave-like character and the particle-like interaction properties. Their surprising discovery has had an enormous impact on the field of nonlinear mathematics and science.

In many physical applications, however, the use of the word *soliton* has come to rely on observation of long-lived solitary waves, with little emphasis placed on interaction properties. Jupiter's Great Red Spot is often described as a soliton due to its long-lived identity (observed over hundreds of years) and the fact that it appears to maintain its identity through interaction with other disturbances. However, recent studies indicate that such Jovian vortices do not keep their identity through intrazonal interactions. In nonlinear optics, the deduction of stable, long-lived solitary waves is of great physical interest for their application as coherent light signals propagating through optical fibers, while their interaction properties are secondary. The definition of the word *soliton* in some dictionaries has come to reflect such usage by physicists, omitting the requirement of interaction. However, for mathematicians, the many surprising and miraculous discoveries of soliton theory are tied

fundamentally to the special interaction properties so its definition always contains elastic interaction as an essential requirement.

The preservation of identity through interaction would not be surprising if we were describing solutions of linear nondispersive wave equations. A simple example is the linear wave equation $u_{tt} + c^2 u_{xx} = 0$, where c is a constant (assumed positive). The general solution is given by $u(x, t) = f(x - ct) + g(x + ct)$, where f and g are determined by initial conditions. The first part, $f(x - ct)$, is a wave traveling to the right with speed c , while the second part, $g(x + ct)$, is a wave traveling to the left with speed c . Two such wave profiles interact when they meet head-on but they both come out of the interaction with the same shape and speed.

However, until the discovery of solitons, it was generally believed that no such property could hold for nonlinear equations. Common understanding in mathematics and physics in the 1950s suggested that nonlinear wave solutions either break, dissipate, or thermalize, that is, distribute initial energy between different solutions over time, and, therefore, lose their identities with time. Much of this understanding was based on prototypical examples, such as the inviscid Burgers equation

$$\frac{\partial u}{\partial t} + u \frac{\partial u}{\partial x} = 0, \quad (1)$$

which describes the one-dimensional propagation of compression waves in gas or dust or automobile traffic. For the initial condition $u(x, 0) = u_0(x)$, the solution is a wave, given implicitly by $u(x, t) = u_0(x - t u(x, t))$. If the initial wave profile $u_0(x)$ has a part with negative slope, the wave front steepens and eventually breaks in finite time, just like ocean waves do at a beach. (The break up time is easy to find by differentiating the solution with respect to x .)

In 1965, Zabusky and Kruskal published numerical studies of the solutions of the Korteweg–de Vries (KdV) equation

$$\frac{\partial u}{\partial t} + u \frac{\partial u}{\partial x} + \delta^2 \frac{\partial^3 u}{\partial x^3} = 0, \quad (2)$$

which changed the above-described common beliefs about nonlinear waves forever (See **Solitons, a brief history**). If $\delta \rightarrow 0$, the limiting equation is the inviscid Burgers equation. Zabusky and Kruskal labeled Equation (2) as (1), chose $\delta = 0.022$ and the initial condition $u(x, 0) = \cos(\pi x)$ and studied its periodic solutions numerically. The word *soliton* was used for the first time in their paper of 1965, in the following extract.

(I) Initially, the first two terms of Eq. (1) dominate and the classical overtaking phenomenon occurs; that is, u steepens in regions where it has negative slope. (II) Second, after u has steepened sufficiently, the third term becomes important and serves to prevent the

formation of a discontinuity. Instead, oscillations of small wavelength (of order δ) develop on the left of the front. The amplitudes of the oscillations grow, and finally each oscillation achieves an almost steady amplitude (that increases linearly from left to right) and has the shape of an individual solitary-wave of (1). (III) Finally, each “solitary wave pulse” or *soliton* begins to move uniformly at a rate (relative to the background value of u from which the pulse rises) that is linearly proportional to its amplitude. Thus, the solitons spread apart. Because of the periodicity, two or more solitons eventually overlap spatially and interact nonlinearly. Shortly after the interaction they reappear virtually unaffected in size or shape. In other words, solitons “pass through” one another without losing their identity.

A standard form of the KdV equation is

$$\frac{\partial u}{\partial t} + 6u \frac{\partial u}{\partial x} + \frac{\partial^3 u}{\partial x^3} = 0. \quad (3)$$

This is equivalent to Equation (2) under a scaling transformation; that is, $u(x, t) \mapsto 6\delta^{2/3} u(x\delta^{-2/3}, t)$ maps any solution of (2) to one of (3). If we consider the initial value problem for the KdV equation on the whole real x -line and look for solutions that vanish at infinity, then solitons are characterized by the initial condition

$$u(x, 0) = N(N + 1)k^2 \operatorname{sech}^2(kx), \quad (4)$$

where N is any nonnegative integer. The corresponding solutions are called N -soliton or multisoliton solutions. The case $N = 1$ gives the traveling wave solution

$$u(x, t) = 2k^2 \operatorname{sech}^2(k(x - 4k^2 t)), \quad (5)$$

often called the one-soliton solution of the KdV equation. It is equivalent to the solitary wave observed by John Scott Russell in 1834 and deduced mathematically by Diederik Korteweg and Hendrik de Vries in 1895 (See **Solitons, a brief history**).

When $N \geq 2$ and time t is considered to be large negative (a long time into the past) or large positive (a long time into the future), the solution separates into a chain of N distinct, localized one-soliton solutions each having the form (5) for some value of k . The chain is positioned far to the left if t is negative or far to the right if t is positive. Each wave in the chain has a distinct height related to its speed. If their phases are arranged so that a taller soliton is to the left of a shorter one at some time in the past, then the taller one overtakes the shorter one, and reappears to the right with its distinctive height, shape, and speed unchanged. The only explicit sign that interaction has occurred is a phase shift, visible asymptotically as x and t become large, in each soliton. As in the one-soliton case, explicit formulae can be found for the N -soliton solution for all x and t . Moreover, the phase shifts due to pairwise interactions can be calculated exactly (See **N -soliton formulas**).

The soliton solutions of the KdV equation can be obtained explicitly by using the inverse scattering method. This method associates each solution $u(x, t)$ of Equation (3), that vanishes (faster than $1/x$) as $x \rightarrow \pm \infty$, to the stationary Schrödinger equation

$$\psi_{xx} + (u(x, t) + \lambda)\psi = 0, \quad (6)$$

where $u(x, \cdot)$ plays the role of the potential function and λ is a parameter. If we let $\lambda = \zeta^2$, we can characterize the space of solutions $\psi(x; \zeta)$ near infinity (in x) in terms of linear combinations of $\exp(\pm i \zeta x)$. (Since u vanishes there, the equation becomes simply $\psi_{xx} - \zeta^2 \psi = 0$, which has such exponentials as solutions.) Quantum mechanical convention regards the solution with behavior $\exp(i \zeta x)$ at $x = +\infty$ as an *incoming wave* from $+\infty$. Part of this incoming wave reflects off the potential barrier u while part of it is transmitted through to the other side. Not all boundary conditions at infinity can be satisfied without imposing conditions on ζ . A discrete set of eigenvalues $\{\zeta_i\}$ arises when we demand that the solutions vanish at infinity. The corresponding solutions are called bound states and their amplitudes are usually normalized. The collected information about discrete eigenvalues, the normalization constants, the reflection coefficient, and the transmission coefficient is called the set of spectral or scattering data. A beautiful and fundamental result of soliton theory is that the time evolution of the spectral data can be obtained explicitly as the potential evolves according to the KdV equation. Another fundamental result is that such evolved spectral data can be inverted to give the solution $u(x, t)$ of the KdV equation at a later time.

If all waves ψ are transmitted, with none being reflected, the potential u is called a *reflectionless* potential. It is an amazing fact that the N -soliton solutions of the KdV equation are precisely the reflectionless potentials of Equation (6).

Another way to find the N -soliton solutions of the KdV is through its Bäcklund transform (See **Bäcklund transformations**) or equivalently the Darboux transform of the Schrödinger equation (6). The latter was introduced by Gaston Darboux in 1882, and expanded in his four-volume lecture notes on the geometry of surfaces (Darboux, 1915). The Darboux transform relates the potentials of two copies of the Schrödinger equation whose solutions are related linearly. His method shows how to change a potential so that a new discrete eigenvalue is added to those of the old potential (See **Darboux transformation**).

Many other nonlinear PDEs are now known to have soliton solutions. Solitons come in different shapes and many flavors (See **Solitons, types of**). The sine-Gordon equation

$$\frac{\partial^2 u}{\partial x^2} - \frac{\partial^2 u}{\partial t^2} = \sin u \quad (7)$$

has N -soliton solutions that asymptote to constants as $x \rightarrow \pm \infty$. One-soliton solutions can be one of two types, called a “kink” or an “anti-kink,” according to whether it decays to zero to the left or the right, respectively. The explicit expression for such solutions is

$$u(x, t) = 4 \arctan \left(\exp \left(\pm \frac{x - \eta t - x_0}{\sqrt{1 - \eta^2}} \right) \right). \quad (8)$$

The “+” choice gives a kink and the “−” choice an antikink. Multisoliton solutions decompose into a sequence of kinks and antikinks as x and t approach $\pm \infty$.

There is another type of soliton admitted by the SG equation, which appears to make it unique within the class of nonlinear Klein–Gordon equations: $u_{xx} - u_{tt} = F(u)$. This is the “breather” solution:

$$u(x, t) = 4 \arctan \left(\frac{\sqrt{1 - \omega^2}}{\omega} \frac{\sin(\omega t)}{\cosh(\sqrt{1 - \omega^2}(x - x_0))} \right). \quad (9)$$

This solution oscillates (or “breathes”) while staying in the same location as time evolves. However, because SG is invariant under the Lorentz transform: $(x, t) \mapsto (X, T)$, $X = (x - ct)/\sqrt{1 - c^2}$, $T = (t - cx)/\sqrt{1 - c^2}$, where c is constant, the breather can be transformed to one that moves with speed $|c| < 1$. The existence of such spatially localized, temporally periodic solutions is rare for nonlinear wave equations.

The nonlinear Schrödinger (NLS) equation

$$i \frac{\partial u}{\partial t} + \frac{\partial^2 u}{\partial x^2} + 2|u|^2 u = 0 \quad (10)$$

provides a third example of a nonlinear PDE with N -soliton solutions. Its one-soliton solution is given by

$$u(x, t) = a \exp(i \eta x + (a^2 - \eta^2)t) \times \operatorname{sech} \left(a(x - 2\eta t - x_0) \right). \quad (11)$$

Solitons are not confined to partial differential equations. A differential-difference equation such as the Toda equation

$$\frac{\partial^2 u_n}{\partial t^2} = \exp(-(u_n - u_{n-1})) - \exp(-(u_{n+1} - u_n)), \quad (12)$$

also has N -soliton solutions for arbitrary positive integers N . See Ablowitz & Segur (1981) for inverse scattering theory extended to such discrete evolution equations.

There also exist nonlinear PDEs that have solutions that can be interpreted as 2-soliton solutions, but which

do *not* have N -soliton solutions for integer $N > 2$. Hirota pointed this out after inventing a method of calculating solitons explicitly and directly without using the inverse scattering method or Bäcklund transformations. (For details, see Ablowitz & Segur (1981) and **Hirota's method**.) An example is the two-dimensional version of the SG equation

$$\frac{\partial^2 u}{\partial x^2} + \frac{\partial^2 u}{\partial y^2} - \frac{\partial^2 u}{\partial t^2} = \sin u. \quad (13)$$

Hirota's method shows that there is a traveling wave solution that can be interpreted as a two-soliton. However, no N -soliton solution with higher N appears to exist.

There are many more equations with solitary waves than those with N -soliton solutions. Traveling waves may also be known to exist without having an exact expression. An example is provided by the reduced model of nerve transmission given by the Fitzhugh–Nagumo equation (See **FitzHugh–Nagumo equation**).

It can be shown that (for a certain range of parameter values) this equation admits traveling waves that are solitary waves. However, energy is not conserved for nerve impulses while it is for solitons.

Despite their rarity in the class of differential equations, soliton equations arise ubiquitously as models of nature. The KdV equation arises as a canonical model of water waves, under certain constraints. Consider the motion of surface waves in a fluid that is inviscid and nondispersive to leading order. Assume that the height of the waves is small compared with the depth of fluid, which in turn is much smaller than the length scale in one direction (x , say) and, moreover, that these two small ratios of scales balance. Then the resulting model is always given by the KdV equation (or its relations, such as the modified KdV equation). See Ablowitz & Segur (1981) for a detailed derivation. The soliton solutions, in the case when dimensionless surface tension is less than $\frac{1}{3}$, are the waves that travel on and raise the free surface. The general solutions are composed of N -solitons and a part called *radiation* that decays in amplitude as it moves away to infinity. When the water waves are nearly two-dimensional, the model equation becomes the Kadomtsev–Petviashvili equation

$$\frac{\partial}{\partial x} \left(\frac{\partial u}{\partial t} + 6u \frac{\partial u}{\partial x} + \frac{\partial^3 u}{\partial x^3} \right) + \frac{\partial^2 u}{\partial y^2} = 0, \quad (14)$$

which also possesses N -soliton solutions. Since such models always arise in an asymptotic sense (e.g., the balance of small wave height to depth of fluid), stability of solutions under perturbation is important. Solitons are stable under perturbations.

Stratified fluids are another context in which the KdV equation arises as a universal model. Consider a situation where a lower, heavier fluid rests on an impermeable solid with a lighter fluid on top that has a

free surface above. A common example is the stratified ocean where colder, denser water lies underneath a warmer, lighter layer. If the sea is contained by a boundary that restricts the colder layer but there are forces present, such as tides, that force the lighter layer, interface waves appear between the two layers. Such waves are also governed by the KdV equation under appropriate assumptions. The soliton solutions are then interface waves that thicken the upper layer. The KdV and its solitons also arise in collision-free hydromagnetic waves, ion-acoustic waves, plasma physics, and lattice dynamics.

Like the KdV equation, the SG and NLS equations also arise as universal models in certain contexts. Some of the applications of the SG equation include the study of propagation of crystal defects, that of domain walls in ferromagnetic and ferroelectric materials, as a one-dimensional model for elementary particles, self-induced transparency of short optical pulses, and propagation of quantum units of magnetic flux on long Josephson (superconducting) transmission lines. See Scott (2003) for detailed descriptions. The NLS equation appears as a model of the propagation of packets of hydrodynamic waves on deep water, nonlinear pulses of light in an optical fibre, two-dimensional self-focusing of a plane wave, one-dimensional self-modulation of a monochromatic wave, propagation of a heat pulse in a solid, and Langmuir waves in plasmas.

SOLITONS, A BRIEF HISTORY

In 1834, a young engineer named John Scott Russell was conducting experiments on the Union Canal (near Edinburgh, Scotland) to measure the relationship between the speed of a canal boat and its propelling force, with the aim of finding design parameters for conversion from horse power to steam. One August day, a rope parted in his apparatus and (Russell, 1844)

Figure 1. A hydrodynamic solitary wave (or soliton) in a tank similar to that described by John Scott Russell (1844). The wave is generated by suddenly releasing (or displacing) a mass of water at the left-hand side of the tank.

the boat suddenly stopped—not so the mass of water in the channel which it had put in motion; it accumulated round the prow of the vessel in a state of violent agitation, then suddenly leaving it behind, rolled forward with great velocity, assuming the form of a large solitary elevation, a rounded, smooth and well-defined heap of water, which continued its course along the channel without change of form or diminution of speed.

Russell did not ignore this serendipitous phenomenon, but “followed it on horseback, and overtook it still rolling on at a rate of some eight or nine miles an hour, preserving its original figure some thirty feet long and a foot to a foot and a half in height” until the wave became lost in the windings of the channel. He continued to study the solitary wave in tanks and canals over the following decade, finding it to be an independent dynamic entity moving with constant shape and speed.

Using a wave tank, he demonstrated four facts Russell (1844). First, solitary waves have a hyperbolic secant shape. Second, a sufficiently large initial mass of water produces two or more independent solitary waves. Third, solitary waves cross each other “without change of any kind.” Finally, a wave of height h and traveling in a channel of depth d has a velocity given by the expression $\sqrt{g(d+h)}$ (where g is the acceleration of gravity), implying that a large amplitude solitary wave travels faster than one of low amplitude.

Although soon confirmed by observations on the Canal de Bourgogne near Dijon, most subsequent discussions of the hydrodynamic solitary wave missed the physical significance of Russell’s observations. Evidence that Russell maintained a deeper appreciation of the importance of his discovery is provided by a posthumous work where—among several provocative ideas—he correctly estimated the height of the Earth’s atmosphere from the fact (well known to military engineers of the time) that “the sound of a cannon travels faster than the command to fire it” (Russell, 1885).

In 1895, Diederik Korteweg and Hendrik de Vries published a theory of shallow water waves that reduced Russell’s problem to its essential features. One of their results was the nonlinear partial differential equation

(PDE)

$$\frac{\partial u}{\partial t} + c \frac{\partial u}{\partial x} + \varepsilon \frac{\partial^3 u}{\partial x^3} + \gamma u \frac{\partial u}{\partial x} = 0, \quad (1)$$

which would play a key role in soliton theory (Korteweg & de Vries, 1895). In this equation, $u(x, t)$ is the wave amplitude, $c = \sqrt{gd}$ is the speed of small amplitude waves, $\varepsilon \equiv c(d^2/6 - T/2\rho g)$ is a dispersive parameter, $\gamma \equiv 3c/2d$ is a nonlinear parameter, and T and ρ are, respectively, the surface tension and the density of water. In general, Equation (1) is nonlinear with exact traveling-wave solutions

$$u(x, t) = h \operatorname{sech}^2[k(x - vt)], \quad (2)$$

where $k \propto \sqrt{h}$ implying that higher amplitude waves are more narrow. With this shape, the effects of dispersion balance those of nonlinearity at an adjustable value of the pulse speed; thus, the hydrodynamic solitary wave is seen to be an independent dynamic entity.

Bäcklund Transformations

Although unrecognized at the time, such an energy conserving solitary wave is related to the existence of a transform technique that was proposed by Albert Bäcklund in 1855 (Lamb, 1976). Under this Bäcklund transformation (BT), a known solution generates a new solution through an integration, after which the new solution can be used to generate yet another new solution, and so on. It is straightforward to find a BT for any linear PDE, which introduces a new eigenfunction into the total solution with each application of the transformation. Only special nonlinear PDEs have BTs, but 19th century mathematicians knew that these include

$$\frac{\partial^2 u}{\partial \xi \partial \tau} = \sin u, \quad (3)$$

which arose in research on the geometry of curved surfaces (Steuerwald, 1936).

In 1939, Yakov Frenkel and Tatiana Kontorova introduced a seemingly unrelated problem arising in solid state physics to model dislocation dynamics in a crystal (Frenkel & Kontorova, 1939). From this study, an equation describing dislocation motion is

$$\frac{\partial^2 u}{\partial x^2} - \frac{\partial^2 u}{\partial t^2} = \sin u, \quad (4)$$

where $u(x, t)$ is atomic displacement in the x -direction and the sine function represents periodicity of the crystal lattice. A traveling-wave solution of Equation (4), corresponding to the propagation of a dislocation, is

$$u(x, t) = 4 \arctan \left[\exp \left(\frac{x - vt}{\sqrt{1 - v^2}} \right) \right], \quad (5)$$

with velocity v in the range $(-1, +1)$. Because Equation (4) is identical to Equation (3) after an

independent variable transformation, exact solutions involving arbitrary numbers of dislocation components as in Equation (5) can be generated through a succession of Bäcklund transformations, but this was not known to Frenkel and Kontorova.

Numerical Discoveries of the Soliton

In the late 1940s, Enrico Fermi, John Pasta, and Stan Ulam (FPU) suggested one of the first scientific problems to be assigned to the Los Alamos MANIAC computing machine: the dynamics of energy equipartition in a slightly nonlinear crystal lattice, which is related to thermal conductivity. The system they chose was a chain of equal mass particles connected by slightly nonlinear springs, and it was expected that if all the initial energy were put into a single vibrational mode, the small nonlinearity would cause a gradual progress toward equal distribution of the energy among all modes (thermalization). But the numerical results were surprising. If all the energy is originally in the mode of lowest frequency, it returns almost entirely to that mode after a period of interaction among a few other low frequency modes. In the course of several numerical refinements, no thermalization was observed (Fermi et al., 1955).

Pursuit of an explanation for this “FPU recurrence” led Zabusky and Kruskal to approximate the nonlinear spring-mass system by the KdV equation. In 1965, they reported numerical observations that KdV solitary waves pass through each other with no change in shape or speed, and coined the term *soliton* to suggest this particle-like property (Zabusky & Kruskal, 1965).

Zabusky and Kruskal were not the first to observe nondestructive interactions of energy conserving solitary waves. Apart from Russell’s tank measurements, Perring and Skyrme had studied solutions of Equation (4) comprising two solutions as in Equation (5) undergoing a collision. In 1962, they published numerical results showing perfect recovery of shapes and speeds after a collision and went on to discover an exact analytical description of this phenomenon (Perring & Skyrme, 1962).

This result would not have surprised 19th-century mathematicians; it is merely the second member of the hierarchy of solutions generated by a BT. Nor would it have been unexpected by Seeger and his colleagues, who had noted in 1953 the connections between the 19th-century work (Steuerwald, 1936) and the studies of Frenkel and Kontorova (Seeger et al., 1953). Because Perring and Skyrme were interested in Equation (4) as a nonlinear model for elementary particles of matter, however, the complete absence of scattering may have been disappointing.

Throughout the 1960s, Equation (4) arose in a variety of problems, including the propagation of ferromagnetic domain walls, self-induced transparency

in nonlinear optics, and the propagation of magnetic flux quanta in long Josephson transmission lines. Eventually it became known as the “sine-Gordon” (SG) equation—a nonlinear version of the Klein–Gordon equation: ($u_{xx} - u_{tt} = u$).

Perhaps the most important contribution made by Zabusky and Kruskal in their 1965 paper was to recognize the relation between nondestructive soliton collisions and the riddle of FPU recurrence. Viewing KdV solitons as independent and localized dynamic entities, they explained the FPU observations as follows. The initial condition generates a family of solitons with different speeds, moving apart in the x - t plane. Since the system studied was of finite length with perfect reflections at both ends, the solitons could not move infinitely far apart; instead, they eventually reassembled in the x - t plane, approximately recreating the initial condition after a surprisingly short “recurrence time.”

By 1967, this insight had led Gardner, Greene, Kruskal, and Miura (GGKM) to devise a nonlinear generalization of the Fourier transform method for constructing solutions of the KdV emerging from arbitrary initial conditions (Gardner et al., 1967). Called the inverse scattering method (ISM), this approach proceeds in three steps. First, the nonlinear KdV dynamics are mapped onto an associated linear scattering problem, where each eigenvalue of the linear problem corresponds to the speed of a particular KdV soliton. Second, the time evolution of the associated linear scattering data is computed. Finally, an inverse scattering calculation determines the time evolved KdV dynamics from the evolved scattering data. Thus, the solution of a nonlinear problem is found from a series of linear computations.

Toda Lattice Solitons

Another development of the 1960s was Morikazu Toda’s discovery of exact two-soliton interactions on a nonlinear spring-mass system (Toda, 1967). As in the FPU system, equal masses were assumed to be interconnected with nonlinear springs, but Toda chose the potential

$$\left(\frac{a}{b}\right) [e^{-bu_j} - 1] + au_j, \quad (6)$$

where $u_j(t)$ is the longitudinal extension of the j th spring from its equilibrium value and both a and b are adjustable parameters. (In the limit $a \rightarrow \infty$ and $b \rightarrow 0$ with ab finite, this reduces to the quadratic potential of a linear spring. In the limit $a \rightarrow 0$ and $b \rightarrow \infty$ with ab finite, it describes the interaction between hard spheres.) Thus by the late 1960s, it was established that solitons were not limited to PDEs; local solutions of difference-differential equations could also exhibit the unexpected properties of unchanging shapes and speeds after collisions.

A Seminal Workshop

These events are only the salient features of a growing panorama of nonlinear wave activities that became gradually less parochial during the 1960s. Solid state physicists began to see relationships between their solitary waves (magnetic domain walls, self-shaping pulses of light, quanta of magnetic flux, polarons, etc.), and those from classical hydrodynamics and oceanography, while applied mathematicians began to suspect that the ISM (originally formulated by GGKM for the KdV equation) might be used for a broader class of nonlinear wave equations. It was amid this intellectual ferment that the first soliton research workshop was organized during the summer of 1972 (Newell, 1974). Interestingly, one of the most significant contributions to this conference came by post. From the Soviet Union arrived a paper by Vladimir Zakharov and Alexey Shabat formulating the ISM for the nonlinear PDE Zakharov & Shabat (1972)

$$i \frac{\partial u}{\partial t} + \frac{\partial^2 u}{\partial x^2} + 2|u|^2 u = 0. \quad (7)$$

In contrast to KdV, SG, and the Toda lattice, the dependent variable in this equation is complex rather than real, so the evolutions of two quantities (magnitude and phase of u) are governed by the equation. This reflects the fact that Equation (7) is a nonlinear generalization of a linear equation $iu_t + u_{xx} + u = 0$, solutions of which comprise both an envelope and a carrier wave. As this linear equation is a Schrödinger equation for the quantum mechanical probability amplitude of a particle (like an electron) moving through a region of uniform potential, it is natural to call Equation (7) the nonlinear Schrödinger (NLS) equation. When the NLS equation is used to model classical wave packets in such fields as hydrodynamics, nonlinear acoustics, and plasma waves, however, its solutions are devoid of quantum character.

Upon appreciating the Zakharov and Shabat paper, participants left the 1972 workshop aware that four nonlinear equations (KdV, SG, NLS, and the Toda lattice) display solitary wave behavior with the special properties that led Zabusky and Kruskal to coin the term *soliton* (Newell, 1974). Within two years, ISM formulations had been constructed for the SG equation and also for the Toda lattice.

Since the mid-1970s, the soliton concept has become established in several areas of applied science, and dozens of nonlinear systems are now known to be integrable through the ISM. Thus, one is no longer surprised to find stable spatially localized regions of energy, balancing the opposing effects of nonlinearity and dispersion and displaying the essential properties of objects.

SOLITONS, TYPES OF

Solitons are localized solutions of nonlinear partial or difference-differential equations that preserve their integrity under collisions with other such solutions. In general, energy is conserved for soliton systems; thus, they are a special class of Hamiltonian systems. Localization may result from a dynamic balance between the effects of nonlinear and dispersion (nontopological solitons) or from a topological constraint.

Nontopological Solitons

Perhaps the most famous example among equations admitting solitary wave solution is the Korteweg-de Vries (KdV) equation

$$u_t + \alpha u u_x + u_{xxx} = 0, \quad (1)$$

which has the solitary-wave solution

$$u = a \operatorname{sech}^2 \left\{ \sqrt{\alpha/12} [x - (a\alpha/3)t] \right\}, \quad (2)$$

where a is the wave amplitude. The quadratic nonlinear term ($\alpha u u_x$) is balanced by the dispersive term (u_{xxx}) in the solution of Equation (2). A feature of such solitary waves of this type is that they preserve their shapes and speeds under collisions (act as particles); thus they are called "solitons."

In general, Equation (1) approximates a more detailed physical description. When the quadratic nonlinear term is small, the cubic nonlinear term may be taken into account, leading to the following equation.

$$u_t + \alpha u u_x + \beta u^2 u_x + u_{xxx} = 0, \quad (3)$$

which is known as the extended Korteweg-de Vries (eKdV) equation. With $\alpha = 0$ and $\beta = 6$, Equation (3) is known as the modified Korteweg-de Vries (mKdV) equation with negative dispersion,

$$u_t + 6u^2 u_x + u_{xxx} = 0. \quad (4)$$

Equation (4) admits solitary wave solutions tending to u_0 at infinity (Grimshaw et al., 1999),

$$u(x, t) = u_0 + \frac{2v^2}{u_0 + \sigma \lambda \cosh[2v(x - \mu t)]}, \quad (5)$$

where $\lambda > |u_0|$, $v = \sqrt{\lambda^2 - u_0^2}$, $\sigma = \pm 1$, $\mu = 2u_0^2 + 4\lambda^2$, and

$$u(x, t) = u_0 - \frac{4u_0}{1 + 4u_0^2(x - 6u_0^2 t)^2}. \quad (6)$$

Equation (5) reduces to a soliton solution as $u_0 \rightarrow 0$,

$$u = 2\sigma \lambda \operatorname{sech}[2\lambda(x - 4\lambda^2 t)], \quad (7)$$

which is different from the KdV soliton solution (2). Equation (6) shows that the wave shape ($u - u_0$) vanishes algebraically as $|x| \rightarrow \infty$. We call it an *algebraic soliton* or *rational soliton*.

The eKdV equation (3) has the following solitary-wave solution ((Grimshaw et al., 1999),

$$u(x, t) = \frac{(6\gamma^2/\alpha)}{1 + B \cosh[\gamma(x - \gamma^2 t)]}, \quad (8)$$

where $B^2 = 1 + (6\gamma^2/\alpha^2)$ and γ is an arbitrary parameter, characterizing the inverse width of the solitary wave. In the case $\beta < 0$ ($0 < B < 1$), at small wave amplitudes ($B \rightarrow 1$), Equation (8) transforms into the KdV soliton solution. On the other hand, as the wave

Figure 1. Interaction between line soliton and periodic soliton.

amplitude increases ($B \rightarrow 0$), it approaches the critical value $a_{cr} = \alpha/|\beta|$. In the limit ($B \rightarrow 0$), the width of the solitary wave increases to infinity and it becomes the so-called *thick soliton*. The thick soliton can be viewed as a kink-antikink combination.

An extension of the KdV equation to motion in two space dimensions was given by Kadomtsev and Petviashvili in order to discuss the stability of the KdV soliton (line soliton in two-dimensional space) against a long transverse disturbance. This two-dimensional extension is known as the Kadomtsev-Petviashvili (KP) equation,

$$(u_t + 6uu_x + u_{xxx})_x + 3su_{yy} = 0, \quad (9)$$

which corresponds to the case of negative and positive dispersion when $s = +1$ and $s = -1$, respectively (Kadomtsev & Petviashvili, 1970). They have shown that the line soliton is stable in the case of negative dispersion and is unstable for the positive dispersion. This leads to the conjecture that a localized soliton in two-dimensional space should be formed in the positive dispersion case, since the line soliton is unstable. Such a soliton solution has been found by Manakov et al. (1977) and Ablowitz & Satsuma (1978), which is no longer exponential in character, but a rational function of space variables,

$$u = 4 \frac{(L + L^*)^{-2} - \xi^2 + \eta^2}{[(L + L^*)^{-2} + \xi^2 + \eta^2]^2}, \quad (10)$$

with

$$\begin{aligned} \xi &= \operatorname{Re}\{x - 2iLy - 12L^2 t\} + \xi_0, \\ \eta &= \operatorname{Im}\{x - 2iLy - 12L^2 t\} + \eta_0, \end{aligned}$$

where ξ_0 and η_0 are arbitrary constants and $*$ indicates the complex conjugate. This solution decays like $(x^2 + y^2)^{-1}$ as $(x^2 + y^2)^{1/2} \rightarrow \infty$; thus, it is also called an *algebraic soliton* or *rational soliton* or *lump*. Another type of localized soliton appears in the positive dispersion case as a sequence of infinite algebraic solitons, called a *periodic soliton* or *soliton chain* (Tajiri & Murakami, 1989). Figure 1 shows a typical interaction between line soliton and periodic soliton.

The Benjamin–Ono (BO) equation,

$$u_t + 4uu_x + \frac{1}{\pi} P \int_{-\infty}^{\infty} \frac{u_{\xi\xi}(\xi, t)}{\xi - x} d\xi = 0, \quad (11)$$

describes a weakly nonlinear, long internal wave in a stratified fluid of great depth, where P stands for the principal value of the integration and the third term is dispersive (Ono, 1975). The BO equation has an algebraic soliton solution,

$$u = \frac{a}{a^2(x - at - x_0)^2 + 1}, \quad (12)$$

which is called a *Benjamin–Ono soliton*.

Envelope solitons

Consider next the propagation of a modulated plane wave in a nonlinear and dispersive medium where the dispersion relation is amplitude dependent, $\omega = \omega(k, |u|^2)$. Expanding around the carrier wave number k_0 and frequency ω_0 , we have

$$\begin{aligned} \omega - \omega_0 = & \left(\frac{\partial \omega}{\partial k} \right)_0 (k - k_0) + \frac{1}{2} \left(\frac{\partial^2 \omega}{\partial k^2} \right)_0 (k - k_0)^2 \\ & + \left(\frac{\partial \omega}{\partial |u|^2} \right)_0 |u|^2 \dots \end{aligned} \quad (13)$$

Replacing $\omega - \omega_0$ by $i\partial/\partial t$ and $k - k_0$ by $-i\partial/\partial x$ and operating on u gives

$$\begin{aligned} i \left\{ \frac{\partial u}{\partial t} + \left(\frac{\partial \omega}{\partial k} \right)_0 \frac{\partial u}{\partial x} \right\} + \frac{1}{2} \left(\frac{\partial^2 \omega}{\partial k^2} \right)_0 \frac{\partial^2 u}{\partial x^2} \\ - \left(\frac{\partial \omega}{\partial |u|^2} \right)_0 |u|^2 u = 0, \end{aligned} \quad (14)$$

which is the nonlinear Schrödinger (NLS) equation. If

$$(\partial^2 \omega / \partial k^2)_0 (\partial \omega / \partial |u|^2)_0 < 0,$$

the plane wave is unstable for the modulation, otherwise it is stable.

Under appropriate scaling and variable transformations, Equation (14) takes the standard form

$$iu_t + u_{xx} + 2\varepsilon |u|^2 u = 0, \quad (\varepsilon = \pm 1). \quad (15)$$

With $\varepsilon = 1$, this is called the focusing NLS (FNLS) equation and has an *envelope soliton* solution,

$$u = K e^{i(\vec{k}x - \vec{\omega}t + \theta)} \operatorname{sech}(Kx - \Omega t + \sigma), \quad (16)$$

where $-(\Omega + i\vec{\omega}) + (K + i\vec{k})^2 = 0$ and θ and σ are arbitrary constants. This is called a *bright soliton* in nonlinear optics (see Figure 2a). If the phase velocity decreases (increases) with increased amplitude, nonlinear effect results in a decrease (increase) of the wave number in the leading half of the envelope and a increase (decrease) in wave number in the trailing half. Thus, the envelope is compressed, and a soliton finds a balance between the effect of

Figure 2. (a) Bright soliton and (b) dark soliton.

compression caused by nonlinearity and broadening caused by dispersion.

The defocusing NLS (DNLS) equation (with $\varepsilon = -1$) has a *dark soliton* solution (shown in Figure 2b)

$$|u|^2 = u_0^2 [1 - a^2 \operatorname{sech}^2 \{u_0 a(x - vt)\}], \quad (17)$$

which appears as an intensity dip in an infinitely extended constant background. The dark soliton solution with $a = 1$

$$|u|^2 = u_0^2 \tanh^2 u_0(x - vt), \quad (18)$$

is called a *black soliton* and the solution with $a < 1$ is sometimes referred to as a *gray soliton*.

Optical communication systems are degraded by the spreading out of pulses as they travel along a fiber, which is caused by dispersion. Hasagawa and Tappert proposed using the nonlinear change of dielectric constant of the fiber to compensate for this dispersive effect (Hasagawa & Tappert, 1973). The optical pulse was shown to form a bright soliton in the case of anomalous dispersion ($\partial^2 \omega / \partial k^2 > 0$), a prediction that was verified by Mollenauer et al. (1980).

Writing $k = k(\omega, |u|^2)$ as the solution of the dispersion relation again leads to the NLS equation but with different variables (ω and k interchanged). The NLS equation in these variables is important in nonlinear optics.

More Space Dimensions

Spatial dark-soliton stripes are experimentally found in the transverse cross section of a continuous-wave (cw) optical beam propagating through material with a self-defocusing nonlinearity. The spatial evolution of a monochromatic transverse electric field $E(x, y, z)$ in a self-defocusing medium with Kerr nonlinearity (the intensity-dependent refractive index $n = n_0 - n_2 |E|^2$) is described by the NLS equation

$$iu_z + \frac{1}{2} \Delta_{\perp} u - |u|^2 u = 0, \quad (19)$$

where $\Delta_{\perp} = \partial_x^2 + \partial_y^2$ is the transverse diffraction operator and z is the propagation coordinate. Although dark-soliton stripes are unstable to transverse long-wavelength modulation, linear analysis predicts stability to transverse modulation having a short period.

Kivshar & Yang (1994) showed that self-defocusing nonlinear media can support a *ring soliton*, which is a dark-solitary wave with ring symmetry. If the ring radius is small enough, it is not subject to the transverse instability characteristic of dark-stripe solitons. It has also been demonstrated that in the small-amplitude limit such solitons are governed by a cylindrical KdV equation. Frantzeskakis and Malomed also showed that *anti-dark ring solitons* (humps on top of the cw background rather than dips) can exist too but only for non-Kerr saturable nonlinearities (Frantzeskakis & Malomed, 1999).

Spatial solitons are optical beams that are self-trapped in space due to a balance between the Kerr nonlinearity and diffraction, a well-studied phenomenon. A new type of spatial soliton, which was proposed by Segev et al. (1992), occurs in a photorefractive (PR) crystal biased with an external dc electric field. The presence of optical beams in a crystal leads to photoexcitation of electric charges. The space charge screens the externally applied electric field in the illuminated area of the crystal. The non-uniform screening of the electric field modifies the refractive index in such a way that the beam becomes self-trapped and propagates in a form of a *PR spatial soliton*. PR spatial solitons can occur at microwatt power levels, whereas the observation of Kerr solitons requires much higher power. Steady solitons in PR crystals are called *screening solitons*.

With the application of a slightly detuned driving field, a slightly lossy Kerr medium supports *cavity solitons*, which are then induced by writing pulses (Firth et al., 2002). This provides an optical means for writing patterns of light onto the cavity cross section and subsequently erasing them, in other words an optical memory.

It is known that the diffusion effect of photoexcited charges leads to a bending of the trajectories of PR solitons. Królikowski et al. (1996) showed by using numerical simulations that *self-bending solitons* in the presence of the diffusion processes are stable and withstand relatively large perturbations. They also showed that even a small contribution of diffusion effect leads to strong energy exchange between colliding PR solitons. In general, spatial solitons in PR media do not satisfy the mathematical definition of solitons, even when they propagate as solitary waves with an unchanging beam profile.

Self-trapping has been studied in Kerr-type, PR, quadratic, and resonant atomic nonlinear media. All of these studies have investigated self-trapping of spatially coherent light beams only. Diffraction of a spatially incoherent beam is larger than that of a coherent beam of the same width. Therefore, a spatially incoherent beam diverges much faster than a coherent beam, and self-trapping of an incoherent beam requires stronger optical nonlinearities than self-trapping a coherent

beam. Recently, self-trapping of incoherent light beams has been demonstrated experimentally (Mitchell et al., 1996) and theoretically (Mitchell et al., 1997). In general, spatial *incoherent solitons* are multimode, self-trapped entities, found only in materials with non-instantaneous (internal) nonlinearity (Mitchell et al., 1997).

Another interesting phenomena is the formation of solitons by the mutual trapping of the interacting waves. Torner et al. (1996) showed that soliton-like propagation occurs in the presence of walk-off between the interacting waves. The solitons in the presence of walk-off are called *walking solitons*. Temporal walk-off is due to different group velocities of the waves forming the soliton, while spatial walk-off is due to different propagation directions of energy and phase fronts in anisotropic media.

The possibility of creating three-dimensional (3-d) localized pulses in a self-focusing medium with anomalous group-dispersion was demonstrated by Silberberg (1990), who showed that they pulses are robust in the sense that remain as separate solitary formations even after collisions. These 3-d-pulses propagating without changes in space or time are called *light bullets*.

Topological Solitons

Another mechanism leading to the emergence of solitons is a topological constraint, exemplified by the sine-Gordon (SG) equation

$$u_{tt} - u_{xx} + m^2 \sin u = 0. \quad (20)$$

The SG equation is characterized by two properties: Lorentz invariance and multiple ground states of the energy. The presence of multiple ground states aids soliton formation because the field takes different asymptotic values on both sides of the isolated wave, so the wave is unable to disperse. (It cannot decay by spreading out for the same reason a twist sealed in the boundary condition at the end of a band cannot be removed.) Thus, wave fields can incorporate *topological solitons* if there are multiple ground states with an appropriate topology. Such a soliton of the SG equation is given by

$$u = 4 \arctan \left[\exp \left(\pm m \frac{x - vt - x_0}{\sqrt{1 - v^2}} \right) \right]. \quad (21)$$

The solution represents a twist in the configuration of the field connecting one ground state $2n\pi$ to the another ground state $(2n \pm 2)\pi$. The $+$ sign and $-$ sign solutions are called a *kink* and an *antikink*, respectively, as shown in Figure 3. They are often termed *soliton* and *antisoliton* instead of kink and antikink. The energy of the SG kink solution is given by $8m/\sqrt{1 - v^2}$,

Figure 3. Kink and antikink.

which has relativistic dependence on the velocity v . There is an analogy between kink/antikink and positively/negatively charged elementary particles. The time evolution of an initial state consisting of two kinks shows that the two kinks move away from each other. On the other hand, the kink and antikink move toward each other. The twist (Q) of a kink ($+2\pi$) or antikink (-2π) is known as its *topological charge*.

Perring and Skyrme were interested in the SG equation as a model equation for physical elementary particles (Perring & Skyrme, 1962). They regarded the kink as nucleon and the linear wave (with $Q=0$) as a meson. The soliton solution of a nuclear model for which topological charge is the baryon number is called a *skyrmion*. Topological charge is a conserved quantity stemming from the geometric configuration of the field—an important feature of many field theories that admit kink solutions.

Numerous attempts were made to find particle-like solutions of relativistically invariant nonlinear field equations in higher dimensions. Under radial symmetry, ring and spherical solitons to the SG and Higgs field equations have been studied numerically by Bogolyubskii and Makhan'kov who called such waves *pulsions* due to their pulsating behavior (Bogolyubskii & Makhan'kov, 1976).

Lattice-solitons

Solitons and kinks in discrete systems are sometimes called *lattice-solitons* and *lattice-kinks*, respectively. The Toda lattice is a one-dimensional lattice of equal masses, interconnected by exponential interaction potentials of the form (Toda, 1981)

$$\phi(r) = \frac{a}{b} \exp(-br) + ar + \text{const.}, \quad (22)$$

where $a, b > 0$ and r is the change of a distance between adjacent masses from its equilibrium value. The equation of motion for Toda lattice is an integrable system, admitting exact N -soliton solutions, whose

form for $N=1$ is given by

$$\exp(-br_n) - 1 = \sinh^2(\kappa) \operatorname{sech}^2 \left(\kappa n \pm t \sqrt{ab/m} \sinh \kappa \right), \quad (23)$$

where κ is an amplitude parameter and m is the mass of the particles.

The theory of wave propagation in periodic structures shows the existence of forbidden frequency bands or band gaps, located around the (Bragg) reflection frequencies. A wave with overtone frequencies within the forbidden frequency bands will have little means of interaction with the periodic structure. The solitons that emerge from a balance between nonlinear self-phase modulation and dispersion associated with the periodic structure are called *gap solitons*.

Other Types of Solitons

A variable coefficient KdV equation arises in the study of a solitary water waves as it enters a region where the bottom is no longer level (Johnson, 1980). A soliton on non-uniform background generally moves with variable speed. When a soliton comes from left (or right) and goes back to left (or right) with opposite velocity—sailing back like an Australian boomerang—it is called a *boomeron*. When a soliton oscillates without ever escaping to infinity, the soliton is referred to as a *trappion* (Calogero & Degasperis, 1982).

The Dym equation ($r_t = r^3 r_{xxx}$) was discovered in unpublished work by Harry Dym and rediscovered in a more general form by Sabatier within the classical string problem. This equation belongs to a wide class of nonlinear equations (WKI equations) found by Wadati, Konno, and Ichikawa to be completely integrable (Wadati et al., 1979). Reciprocal links between the Dym and KdV and MKdV equations provide implicit solutions, since they include the simultaneous change of both dependent and independent variables (Kawamoto, 1985). The Dym equation has *cusp soliton* solutions. Some new approaches, which allow construction of multisoliton solutions almost explicitly have been developed for the Dym equation by (Dmitrieva, 1993). Recently, it was shown that the Dym equation on the complex plane is relevant to such physical problems as the Hele-Shaw problem and the Saffman-Taylor problem (Constantin & Kadanoff, 1991).

The nonlinear transverse oscillation of an elastic beam subject to an end-thrust is described by one of the WKI equations. If the beam is flexible enough, it deforms into a loop, with the upper half portion having negative curvature. In this case, the nonlinear oscillation can be described by an equation of the following form (Konno et al., 1981):

$$y_{xt} + \operatorname{sgn} \left(\frac{ds}{dx} \right) \left(\frac{y_{xx}}{(1 + y_x^2)^{3/2}} \right)_{xx} = 0, \quad (24)$$

Figure 4. Loop soliton.

where s denotes arc length measured around the loop. Konno et al. showed that such a *loop soliton* (shown in Figure 4) propagating along a stretched rope can be obtained as a one soliton solution to Equation (24).

Solitary waves with finitely extended (compact) support were recently studied in various equations with nonlinear dispersion. Rosenau and Hyman showed that solitary-wave solutions may have compact support under the influence of nonlinear dispersion in various generalizations of the KdV equations with nonlinear dispersion (Rosenau & Hyman, 1993). The nonlinear dispersion is weaker for small amplitude than the linear dispersion in the KdV equation, leading to compactification. Such robust soliton-like pulses—characterized by the absence of the infinite tail—are called *compactons*.

SPATIOTEMPORAL CHAOS

Spatiotemporal chaos is a dynamical regime developing in spatially distributed systems lacking long-time, large-distance coherence in spite of an organized regular behavior at the local scale. It is, so to speak, located in the middle of a triangle, the corners of which are temporal chaos, which is prevalent for a few

spatially frozen degrees of freedom, spatial chaos, in disordered time-independent patterns, and turbulence, with cascading processes over a wide range of space and time scales.

Short-term local coherence is usually the result of some instability mechanism that generates dissipative structures of different kinds depending on whether or not a specific frequency ($\omega_c = 0$ or $\neq 0$) and/or a spatial periodicity ($k_c = 0$ or $\neq 0$) is introduced in the system (Cross & Hohenberg, 1993). Examples of spatiotemporal chaos may be found in every combination of these elementary cases: Rayleigh–Bénard convection produces a time-independent cellular pattern ($\omega_c = 0$, $k_c \neq 0$), the Belousov–Zhabotinsky (BZ) reaction-diffusion system is unstable against a homogeneous oscillatory mode ($\omega_c \neq 0$, $k_c = 0$), convection in binary fluid mixtures develops in the form of dissipative waves ($\omega_c \neq 0$, $k_c \neq 0$), and the same holds for hydrothermal waves. Transitions to spatiotemporal chaos have been observed and studied in many experimental systems, including parametrically excited surface waves, electro-hydrodynamic instabilities in nematic liquid crystals (Kramer & Pesch, 1996), and liquid films flowing down inclines (Chang, 1994). Figure 1 (left) illustrates the case of spiral defect chaos in convection.

In practice, confinement effects enter and compete with instability mechanisms in the ordering process. Their intensity can be appreciated through aspect ratios, measuring the physical size of the system in units of the instability wavelength. In small aspect-ratio experiments, confinement effects are effective in the three space directions and chaos is purely temporal. Spatiotemporal chaos develops when confinement is partially relaxed. Accordingly, phenomena developing at surfaces or in thin layers can be understood as (quasi)-two-dimensional (Gollub, 1994). In the same way, narrow channels or oriented media along a specific direction exemplify the case of (quasi)-one-dimensional systems (Davaud, 1994).

A second important classification results from the nature of the bifurcation, either supercritical or subcritical (continuous or discontinuous), which implies either substitution or coexistence of bifurcating and bifurcated states. To a large extent, this feature dictates the type of theory most appropriate to understand the growth of spatiotemporal chaos.

Consider first the supercritical case. When confinement effects are unable to maintain order everywhere, reduced universal descriptions are generically obtained as “envelope equations” (Newell, 1974). Standing as a paradigm, the cubic complex Ginzburg–Landau (CGL3), reviewed by Aranson & Kramer (2002), spatially unfolds a local supercritical Hopf bifurcation signalling the emergence of uniform oscillations ($\omega_c \neq 0$, $k_c = 0$). In one dimension (1-d), this equation reads

$$\partial_t A = A + (1 + i\alpha)\partial_{xx}A - (1 + i\beta)|A|^2A, \quad (1)$$

Figure 1. Left: Spiral defect chaos near threshold in Rayleigh–Bénard convection at $O(1)$ Prandtl number. (Courtesy Ahlers, 1998). Right: Coexistence of spirals and defect mediated chaos in the 2-d CGL equation for $\alpha = -2$ and $\beta \simeq 0.75$ (Manneville, unpublished).

where the parameters α and β measure linear and nonlinear dispersion effects, respectively. The CGL3 equation admits trivial exact solutions in the form of plane waves $A = A_q \exp[i(qx - \omega_q t)]$, with amplitude $A_q = (1 - q^2)^{1/2}$ and angular frequency $\omega_q = \alpha q^2 + \beta(1 - q^2)$, which are stable or unstable depending on the values of α , β , and q . Other nonlinear solutions can exist; in one dimension, solitary waves called Bekki–Nozaki holes are the best known. In two dimensions (2-d) they take the form of spiral waves that are topological defects of the complex order parameter A . Figure 1 (right) illustrates the coexistence of spirals and defect-mediated chaos (see below) in the 2-d CGL equation. Figure 2 displays the different possible steady-state regimes of the 1-d CGL equation in the $(1/\beta, -\alpha)$ plane. In region I, plane waves attract most initial conditions. Phase turbulence is present in region IV slightly beyond the Benjamin–Feir instability (BF) line, as given by Newell’s criterion for “ $q = 0$ ” oscillations (Newell, 1974). In the vicinity of this line, the solution can be written as $A(x, t) = (1 + \varrho(x, t)) \exp(i\theta(x, t))$. The amplitude modulation ϱ , enslaved to the gradient of the phase perturbation θ , remains small, while θ is governed at lowest order by the Kuramoto–Sivashinsky equation (Kuramoto, 1978)

$$\partial_t \theta = D \partial_{xx} \theta - K \partial_{xxx} \theta + g(\partial_x \theta)^2, \quad (2)$$

where $D = 1 + \alpha\beta$ is an effective diffusion coefficient that is negative in the unstable range (Chaté & Manneville, 1994a). Deeper in the unstable domain, in region V, a “revolt” of $|A|$ ends in the formation of defects (phase singularities at zeroes of $|A|$) and amplitude turbulence or defect-mediated turbulence sets in (Coulet et al., 1989). Defects analogous to Bekki–Nozaki holes are observed to evolve in a spatiotemporal intermittent fashion in region II. As suggested by its position in the diagram, the “bi-chaos” regime in region III presents itself as a fluctuating mixture of states in regions IV and V.

Figure 2. Bifurcation diagram of the 1-d CGL equation. (Data from Chaté, 1994.)

By contrast, subcritical instabilities are characterized by the possibility of finding the system in one of several (usually two) states at a given point in space. Short-range coherence then implies the formation of homogeneous domains of each state, separated by fronts (Pomeau, 1986). In gradient systems, these fronts move regularly so as to decrease the potential, but in nongradient systems, they may have more complicated behaviors. A particularly interesting scenario develops when one of the competing local states is a chaotic transient while the other is regular. At a given time, the whole system can be divided into so-called laminar and turbulent domains, and at a given point in space, the system is alternatively laminar or turbulent, hence the name “spatiotemporal intermittency” (STI). According to Pomeau (1986), front propagation is then akin to a time-oriented stochastic process known as “directed percolation” (DP) used to model epidemic processes (Kinzel, 1983). Directed percolation defines a critical phenomenon, with an associated universality class (a specific set of scaling exponents governing the statistical behavior of the system as a function of the distance to threshold).

The existence of separated domains and sharp fronts supports the idea of modeling extended systems in terms of identical subsystems arranged on a regular lattice, each with its own phase space, and coupled to its neighbors. In addition to space discretization, time discretization leads to the definition of coupled map lattices that have served to illustrate several transition scenarios such as cascades of spatial period doublings, defect-mediated regimes (Kaneko, 1993), or STI (Chaté & Manneville 1994b) that make explicit how local transient temporal chaos is converted into sustained spatiotemporal chaos. A last step can be taken by also discretizing the local phase space, which yields cellular automata (Wolfram, 1986). Further randomization of the dynamics then points towards an understanding of the transition to turbulence in statistical physics terms (Kinzel, 1983). Such approaches should help in understanding plane Couette flow, the simplest

shear flow produced by two parallel plates sliding in opposite directions. This configuration is a particularly intriguing example of a subcritical hydrodynamic system where domains of laminar flow, known to be stable for all flow conditions, coexist in a wide range of Reynolds numbers and in continuously varying proportions with domains of small-scale turbulence.

Spatio-temporal chaos definitely relates to the process of transition to turbulence when confinement effects are weak. It appears to occupy a central position at the crossroads of nonlinear dynamics, mathematical stability theory, and statistical physics of many-body systems and non-equilibrium processes, with a wide potential for applications (Rabinovich et al., 2000).

SPECTRAL ANALYSIS

Spectral analysis is a central method in studies of linear systems (which obey the superposition principle), and spectral representations are widely used in acoustics, quantum mechanics, wave propagation, optical spectroscopy, harmonic analysis, and signal processing. If $f(x)$ is a square integrable function on real line, it can be represented in a dual (spectral) space k with the integral transforms (Hildebrand, 1976)

$$f(x) = \frac{1}{2\pi} \int_{-\infty}^{\infty} \hat{f}(k) e^{ikx} dk \quad (1)$$

and

$$\hat{f}(k) = \int_{-\infty}^{\infty} f(x) e^{-ikx} dx. \quad (2)$$

The Fourier transform $\hat{f}(k)$ gives the spectral density of harmonic oscillations e^{ikx} between the wave numbers k and $k+dk$. The inverse Fourier transform $f(x)$ corresponds to a spectral decomposition of a function $f(x)$ over a continuous linear combination of the harmonic oscillations e^{ikx} .

For periodic functions with a period L , such that $f(x+L) = f(x)$, the spectral density has peaks at wave numbers $k = k_n = 2\pi n/L$; that is, the spectral decomposition of a function $f(x)$ becomes a discrete sum of the harmonic oscillations $e^{ik_n x}$:

$$f(x) = \sum_{n=-\infty}^{\infty} \hat{f}_n e^{ik_n x} \quad (3)$$

and

$$\hat{f}_n = \frac{1}{2L} \int_{-L}^L f(x) e^{-ik_n x} dx, \quad (4)$$

where $\hat{f}_n$ are Fourier coefficients of the complex Fourier series for $f(x)$. Thus, depending on properties of a function $f(x)$, it can be decomposed over continuous or discrete spectrum in the Fourier spectral representation.

As an example, the rectangular wave defined as

$$\Delta_\varepsilon(x) = \begin{cases} 1/2\varepsilon, & |x| < \varepsilon, \\ 0, & |x| > \varepsilon \end{cases} \quad (5)$$

can be expressed in the continuous spectral representation with the Fourier transform:

$$\hat{\Delta}_\varepsilon(k) = \frac{1}{2\varepsilon} \int_{-\varepsilon}^{\varepsilon} e^{-ikx} dx = \frac{\sin \varepsilon k}{\varepsilon k}. \quad (6)$$

The power spectrum of a signal is defined as the squared amplitude of its Fourier spectrum: $\hat{R}(k) = |\hat{f}(k)|^2$. Equivalently, the power spectrum is the Fourier spectrum of the autocorrelation function $R(x)$ defined as

$$\begin{aligned} R(x) &= \int_{-\infty}^{\infty} f(x') f(x' - x) dx' \\ &= \frac{1}{2\pi} \int_{-\infty}^{\infty} |\hat{f}(k)|^2 e^{ikx} dk \\ &= \frac{1}{2\pi} \int_{-\infty}^{\infty} \hat{R}(k) e^{ikx} dk. \end{aligned} \quad (7)$$

The autocorrelation function $R(x)$ represents similarities between the function $f(x)$ and itself, and its Fourier transform can be really measured in applications.

A power spectrum measures the energy of a signal between the wave numbers k and $k+dk$. The total energy of a signal is related to the power spectrum by the Parseval formula:

$$E = \int_{-\infty}^{\infty} f^2(x) dx = \frac{1}{2\pi} \int_{-\infty}^{\infty} |\hat{f}(k)|^2 dk = R(0). \quad (8)$$

As a result, the autocorrelation function is bounded as $|R(x)| \leq R(0) = E$.

Linear differential equations, especially initial-value problems for wave equations, can be easily solved with the use of spectral decompositions such as Fourier transforms. In the linear limit, for example, small-amplitude long wave waves are described by the linearized KdV equation:

$$\frac{\partial u}{\partial t} + \frac{\partial^3 u}{\partial x^3} = 0, \quad (9)$$

with initial data: $u(x, 0) = f(x)$. The Fourier transform method represents the solution to this problem as (Ablowitz & Fokas, 1997)

$$u(x, t) = \frac{1}{2\pi} \int_{-\infty}^{\infty} \hat{u}(k, t) e^{ikx} dk, \quad (10)$$

where $\hat{u}(k, 0) = \hat{f}(k)$. Since the Fourier transform $\hat{f}(k)$ has the property $\hat{f}'(k) = ik \hat{f}(k)$, the time evolution of the spectral density $\hat{u}(k, t)$ is trivial,

$$\frac{\partial \hat{u}}{\partial t} - ik^3 \hat{u}(k, t) = 0, \quad (11)$$

with the solution $\hat{u}(k, t) = \hat{f}(k) e^{ik^3 t}$. As a result, the exact solution $u(x, t)$ of the initial-value problem for the linearized KdV equation is a spectral superposition with density $\hat{f}(k)$ of waves $e^{i(kx - \omega(k)t)}$, where

Figure 1. Exact solution $u(x, t)$ of the linear KdV equation in the Fourier spectral representation for $t > 0$, compared with the initial (Gaussian) form $u(x, 0) = e^{-x^2}$.

$\omega(k) = -k^3$ is the dispersion relation. Figure 1 shows the exact solution $u(x, t)$ at a time $t > 0$, which evolves from the initial (Gaussian) form $u(x, 0) = f(x) = e^{-x^2}$.

The inverse scattering transform (IST) extends spectral analysis for solutions of initial-value problems for nonlinear differential equations. For example, a solution of the nonlinear KdV equation

$$\frac{\partial u}{\partial t} + \frac{\partial^3 u}{\partial x^3} - u \frac{\partial u}{\partial x} = 0, \quad (12)$$

such that $u(x, 0) = f(x)$ is related to the spectrum of the stationary Schrödinger equation on a real line of x with a t -dependent potential $u(x; t)$ (Ablowitz et al., 1974)

$$-\psi''_{\lambda}(x) + u(x; t)\psi_{\lambda}(x) = \lambda\psi_{\lambda}(x). \quad (13)$$

If $f(x)$ is a square integrable function on real line, the spectral data consists of the continuous spectrum at $\lambda = k^2 \geq 0$ with eigenfunctions $\psi_{\lambda} = \Psi(x; k)$ and a finite discrete spectrum at $\lambda = -p_n^2 < 0$ with eigenfunctions $\psi_{\lambda} = \Psi_n(x)$. The spectral decomposition of the potential $u(x; t)$ over eigenfunctions of the continuous and discrete spectrum takes the form (Pelinovsky & Sulem, 2000)

$$u(x; t) = \frac{1}{2\pi} \int_{-\infty}^{\infty} \rho(k, t) \Psi(x; k) dk + \sum_n \rho_n(t) \Psi_n(x), \quad (14)$$

where $\rho(k, t)$ and $\rho_n(t)$ are coefficients of the spectral decomposition. The time-evolution of the spectral data has the simple solution

$$\begin{aligned} \rho(k, t) &= \rho(k, 0)e^{ik^3 t}, \\ \rho_n(t) &= \rho_n(0)e^{p_n^3 t}. \end{aligned} \quad (15)$$

The initial values for the spectral data are found from spectral analysis of the stationary Schrödinger equation with the initial potential $u(x; 0) = f(x)$.

SPIN SYSTEMS

Spin systems generally refer to ordered magnetic systems. A feel for how spins behave can be obtained by observing the behavior of two or more small compasses or magnetic needles pinned close to each other but free to rotate in a plane (perpendicular to the north–south direction), so that they align in parallel corresponding to a minimum energy configuration.

Even though magnetism is one of the oldest natural phenomena known, it took many centuries to identify its origin. In 1820, the Danish physicist Hans Oersted observed that electric current flowing through a wire affects a nearby magnet, and it is now known that the motion of an electron in an orbit around the nucleus of an atom is equivalent to a small electric current loop that behaves as an atomic magnet called a magnetic dipole moment. Each electron also possesses a rotation about its own axis, which is identified as electron spin, and is equivalent to a circulating electric current with its own dipole magnetic moment.

More generally, spin angular momentum or spin is an intrinsic property, associated with quantum particles, which does not have a classical counterpart. The magnetic dipole moment due to the spinning motion with spin angular momentum operator S is given by $m_S = -(g\mu_B/\hbar)S$, where g is the gyromagnetic ratio, μ_B is the Bohr magneton and $\hbar = h/2\pi$ is Planck's constant.

Macroscopically, all substances are magnetic to some extent and every material when placed in a magnetic field acquires a magnetic moment. Magnetic materials can be classified in terms of magnetic moment in the absence of an applied field. The magnetic moment is zero for each atom in diamagnetic materials. In the case of paramagnetic materials, for each atom the moment is nonzero but still averages to zero over many atoms. In ferromagnetic materials, the moment of each atom and even the average is not zero (Matis, 1988).

Model	Directional Coefficient
Ising/Potts	$a = b = 0$
XY	$c = 0$
Easy axis exchange anisotropy	$c > a = b$
Easy plane exchange anisotropy	$c < a = b$
Heisenberg	$a = b = c = 1$
XYZ	$a \neq b \neq c$

Table 1. Ferromagnetic models.

Ferromagnetic materials, which are made up of domains, exhibit long-range ordering that causes the spins of the atomic ions to line up parallel to each other in a domain. The underlying interaction originates from an exchange interaction that is caused by the overlapping of electronic wave functions that has no classical analog. The exchange interaction is a quantum phenomenon of electrostatic origin first proposed by Heisenberg, and the Hamiltonian representing spin-spin exchange interaction is given by

$$H_{\text{ex}} = - \sum_{\langle ij \rangle} J_{ij} \mathbf{S}_i \cdot \mathbf{S}_j. \tag{1}$$

Here $\mathbf{S}_i$ is the total spin of all the electrons bound to the atom or ion at the lattice site i . J_{ij} is the phenomenological exchange constant and is positive for ferromagnetic coupling. It is often sufficient to consider only interaction of nearest neighbors, represented by the bracket $\langle ij \rangle$. In the isotropic case J_{ij} is treated as a constant, J .

Different magnetic spin models can be identified by generalizing the Heisenberg Hamiltonian by introducing directional coefficients,

$$H_{\text{ex}} = - \sum_{\langle ij \rangle} [a S_{ix} S_{jx} + b S_{iy} S_{jy} + c S_{iz} S_{jz}]. \tag{2}$$

The underlying models are indicated in Table 1. Among these, the Ising model is the simplest, where the interacting spins can be either parallel or antiparallel. The Potts model is a generalization of the Ising model where the number of spin states is extended to k equally spaced directions in a plane.

Other models involve additional interactions: (i) *magnetocrystalline anisotropy* is due to interaction between the crystal field and the spin-orbit coupling, either of easy axis or of easy plane. (ii) *Zeeman energy*: When a strong external magnetic field $\mathbf{H}$ is applied, the Hamiltonian is modified with the addition of a term $H_Z = -g\mu_B \sum_i \mathbf{S}_i \cdot \mathbf{H}$. (iii) One can also consider interactions such as biquadratic exchange, or weak interactions such as Dzyaloshinski-Moriya type.

There are certain materials for which the exchange integrals J_{ij} become negative. Consequently, the spins align antiparallel to each other so that the net magnetization is zero. These materials are called antiferromagnets and are normally modeled to be made

up of two sublattices. However, if the resulting total magnetization, which is the difference between that of the two sublattices, is nonzero, the material is a ferrimagnet.

A spin glass is another state of magnetism that is different from the long-range ordered ferro- and antiferromagnetic phases. A spin glass phase can be considered as consisting of randomly interacting spins with ferro- or antiferromagnetic coupling between them. The combination of the randomness with the competing or mixed interactions causes frustration. Consequently, the exchange integrals J_{ij} are normally distributed random variables corresponding to the so-called Ruderman, Kittel, Kasuya, and Yoshida (RRKY) interaction. The two famous models that describe spin glass are the Edwards–Anderson (EA) model and the Sherrington–Kirkpatrick (SK) mean field model.

The spin glass theory can also be considered as a statistical model of neural networks. The simple spin glass theory based on the SK model provides a qualitative description of memory. In a neural network, the minimal structure element is a neuron whose state can be described by one real variable, and a simple Ising representation $S_i = \pm 1$ is often used. The problem of neural network systems can be formulated by writing the Hamiltonian in Ising form with the so-called Hebbian learning rule for J_{ij} , which is the Hopfield model (Dotsenko, 1994).

The Bethe ansatz is extremely useful in solving quantum spin chain models and to obtain exact results including ground state and excited states. A chain of spin one-half with spin-spin coupling has been solved using the Bethe ansatz method. However, the quantum mechanical description corresponding to the spin Hamiltonian with higher spin values is extremely complicated because it is difficult to know in which particular state one of the individual spins finds itself. Even in the ground state this is impossible. Hence in these cases, one looks for limiting procedures, either classical or semiclassical.

Owing to the presence of the exchange interaction, a small disturbance in one of the spins will be propagated in the form of spin waves. It can also be regarded as oscillations in the magnetic moment density, propagating through a magnetically ordered crystal. The spin wave energy must be equal to the excitation energy of the crystal required to cause a change in the orientation of the spin. The basic entity of the quantized form of the spin wave is called a magnon.

In semiclassical theories of magnetism it is common to approximate the unwieldy spin operators or matrices (which obey the standard spin commutation relations) by the analogous harmonic oscillator operators. Among the machineries established to handle the spin operators, namely, (i) Holstein–Primakoff (H–P) transformation, (ii) Schwinger–Boson representation, (iii) Dyson–Maleev transformation, and (iv) Jordon–

Wigner transformation. The H-P transformation is the most useful one.

Just like photons and phonons, spin waves are bosons describing collective excitations that involve all the spins to the same degree. The operators $S_n^\pm = S_{nx} \pm iS_{ny}$ act on the ground state as field theoretical creation and annihilation operators. It is, thus, reasonable to change by means of a unitary transformation to operators a and $a^\dagger$ that satisfy the Bose commutation relation $[a_i, a_j^\dagger] = \delta_{ij}$. In this way, one can obtain the H-P transformation of spin operators, which transforms the quantum mechanical spin operators into standard boson operators. In the low-temperature limit, one can use semiclassical expansion for S_n^+ and S_n^- . The Heisenberg equation of motion for the boson operator $i\hbar da_j/dt = [a_j, H]$ when combined with Glauber's coherent state representation for Bose operators in the long wavelength, low temperature limit (continuum limit) leads to nonlinear evolution (partial differential) equations. Specific one-dimensional cases correspond to integrable spin models exhibiting soliton type spin excitations in addition to linear magnons (Kosevich et al., 1991).

Alternatively, in the large spin limit, the quantum description goes over to the classical vector model for spin, so that the spin operator can be replaced by an ordinary vector of length $s(s+1) > s$, which can be treated as a dynamical/canonical variable. For a ferromagnet described by Heisenberg Hamiltonian (Equation (1)) or its generalization, the classical canonical equations for the spins can be obtained in analogy with a spinless nonrelativistic particle, which is a typical nonlinear dynamical system. The resultant equation of motion $d\mathbf{S}_n/dt = \{\mathbf{S}_n, H\}$, where $\{\}$ represents spin Poisson bracket defined for functions of spins under continuum approximation, reduces to the appropriate Landau-Lifshitz (LL) equation. In real magnets, dissipative effects also play an important role, which is included in the LL equation via Gilbert damping. Thus, the LL equation with Gilbert damping (originally derived phenomenologically) is written as

$$\frac{\partial}{\partial t} \mathbf{S}(\mathbf{r}, t) = \mathbf{S} \times \mathbf{F} + \lambda \mathbf{S} \times (\mathbf{S} \times \mathbf{F}),$$

$$\mathbf{S} = (S_x, S_y, S_z), \quad S^2 = 1, \quad (3)$$

where $\mathbf{F}$ is the effective field and λ is the Gilbert damping parameter. A typical form for $\mathbf{F}$ is $\mathbf{F} = J\nabla^2 \mathbf{S} + 2A(\mathbf{S} \cdot \mathbf{n})\mathbf{n} + \mu\mathbf{H}$, where A is the anisotropy parameter, $\mathbf{H}$ is the external magnetic field, and $\mathbf{n}$ is a unit vector.

The Landau-Lifshitz equation is a highly non-trivial vector nonlinear partial differential equation in three spatial dimensions. Several one-dimensional cases (without damping) corresponding to quasi-one-dimensional ferromagnetic spin chains (Mikeska & Steiner, 1991; Kosevich et al., 1991) have been found

to be completely integrable soliton systems. These include the isotropic case, uniaxial, and biaxial as well as circularly symmetric cases and are related to the nonlinear Schrödinger equation (Lakshmanan, 1977), (Lakshmanan et al., 1990) and its generalizations. In two dimensions, instanton and vortex-type structures have been identified. Magnetic spatiotemporal patterns have also been identified in the presence of damping and external oscillating fields.

The study of spin excitations in magnetic systems has numerous potential applications. These include (i) magnetic storage devices such as magnetic disks in computers, (ii) spintronics or spin electronics (microelectronic devices that function using the spin of the electrons), (iii) magnetic microchips (magnetic dots, magnetic waves, and magnetic computers), and (iv) magneto-optical recording. (For details, refer to the special issue on Magneto-electronics, *Physics Today*, April 1995).

SPIRAL WAVES

Rotating spiral waves occur in a wide range of chemical, biological, and physical systems that can be considered as effectively two-dimensional excitable or oscillatory media in which the local nonlinear dynamics exhibits threshold behavior, separating an excited state from a recovered state (Holden et al., 1991). In such a medium, waves of excitation spread without decrement through the stationary medium, with diffusive spread of the excitation from a region triggering excitation of neighboring regions.

A single spiral wave in a large homogeneous medium acts as an organizing center, imposing its pattern throughout the medium. It has the characteristics of

Figure 1. Spiral wave solutions of the FitzHugh–Nagumo equations for an excitable medium: (a) snapshot of solitary spiral wave; (b) intersection of excitation and recovery isolines defining the tip (solid circle), which meanders bip periodically around the central core; and (c) evolving field of wavebreaks.

a field, in that it fills the medium, but it also has a location. The location of a spiral wave is that of its center, variously defined as the central core that is not invaded by the propagating wave, and around which the spiral rotates; or as a phase singularity; or by the tip, defined by where the wave front meets the wave back; or by the intersection of two isolines. For a rigidly rotating spiral in an isotropic medium, the tip encloses a circular core, but even in a homogeneous medium, the tip motion can be complex, meandering quasi-periodically within a bounded region, or hypermeandering in an unbounded region, and any inhomogeneities and boundaries interactions can produce drift (Barkley, 1994). Along any radius far from the core, activity appears as a periodic wave train with a temporal frequency ω (for a rigidly rotating spiral equal to the rotation frequency of the spiral) and spatial wavelength λ . These are generally single-valued functions of the medium parameters. The wave front (or any other isoline) approximates an Archimedean spiral (the involute of a circle) with a pitch λ , as illustrated in Figure 1b. The simple (one-armed) Archimedean rotating spiral in polar coordinates (θ, r) is a periodic function of phase ϕ

$$\phi = \omega t \pm \theta + a(r - r_0) \quad (1)$$

with $a > 0$ giving the wavelength λ and pitch $dr/d\theta|_{\phi=\text{const}}$ equals to $1/a$.

If a stable spiral wave is subject to a parametric perturbation, the form of the spiral will be restored, but its location and phase may be changed; this allows periodic perturbations, at the same frequency as the rotation frequency of the spiral, to produce a directed, resonant drift. A single spiral need not be stable—even in a parametrically homogeneous medium, dynamical heterogeneities produced by the rotating spiral wave can lead to wave breaks, resulting in pairs of new phase singularities that may develop into new spirals, collapse, or be extinguished, giving a spiral wave turbulence as illustrated in Figure 1c. In such an evolving field of wave breaks, the singularities may be considered as defects; are born and annihilate on collision, in pairs with opposite chirality; or exit the medium at boundaries.

The best studied laboratory example of spiral waves is the Belousov–Zhabotinsky reaction, a chemical excitable or oscillatory reaction originally constructed as an organic chemical analogue for oscillatory reactions in a biochemical system, in which the phase of the redox oscillation is monitored by color changes. In a shallow layer of solution in a Petri dish, spirals and interacting spirals can be initiated (Winfree, 1972), and spatiotemporal changes in activity can be monitored optically and quantified (Müller et al., 1987). Winfree’s experimental and numerical modeling of simplified models and caricatures (Winfree, 1991) of two- and three-dimensional excitable systems established much of the phenomenology of spiral wave behavior.

Spiral waves occur in several biological systems. In many cell types there are intracellular waves of calcium, where calcium-induced calcium release provides the positive feedback necessary for excitability. In the slime mold, where the intercellular relaying of a chemotactic signal—cyclic AMP—between individual amoebae by cAMP-induced cAMP release provides the excitability, the social amoebae collect together in a rotating spiral wave and aggregate into a slug, which can then metamorphose into a fruiting body. An important example is from cardiac patho-physiology, where the three-dimensional analogue of a spiral, the scroll, provides the re-entrant propagation that produces high frequency arrhythmias in cardiac muscle and provides the route to ventricular fibrillation and sudden cardiac death.

In physics, spiral waves are found in surface catalysis, nonlinear optical media, and it has been suggested that spiral galaxies represent a rotating spiral wave of star formation and death.

In all these examples, the excitable medium can be modeled by a reaction-diffusion equation, in which only the excitatory variable (as in most biological examples) or both excitatory and recovery variables (as in most chemical examples) have nonzero diffusion coefficients. Spiral wave solutions of mechanistically detailed, high order models, or simplifications, can be obtained by initiation from artificial initial conditions, or by imposing a wave break or wavebreaking dynamical or parametric heterogeneity. Much of the phenomenology can be seen in the simple, two-variable FitzHugh–Nagumo system, or computationally faster simplifications (Zykov, 1987), and reproduced by eikonal equations that describe the dependence of the propagation velocity of the wave front on its curvature (Mikhailov et al., 1994).

STABILITY

The concept of stability lies at the heart of mathematical physics. Although in a perfect environment it might be thought possible to balance a pencil on its point, this is not possible in the real, noisy world—a pencil standing on its point is unstable. Meanwhile a hexagonal pencil lies easily on its side in a stable equilibrium. Intermediate is the pencil standing on its flat end, which can be achieved, albeit with difficulty, because this configuration is metastable, meaning stable against infinitesimally small disturbances, D_S , and unstable against large disturbances, D_L . Notice that under D_S , the pencil has more than one stable equilibrium (multistability). A special case is a circular pencil on its side: if it rolls a little, and it will not come back and so is marginally stable. Generalizing these experiences, a state is declared stable if it is physically observable under D_S ; otherwise, it is unstable.

In 1892, Aleksandr Lyapunov formalized this intuitive idea of stability against D_S by considering free motions of a dynamical system in phase space. Although this ignores external noise, the results agree with more realistic stochastic criteria. Consider a system of n first-order differential equations, $\dot{\mathbf{x}} = \mathbf{f}(\mathbf{x})$, giving a stationary vector field in the phase space spanned by the n components of vector $\mathbf{x}$. Trajectories fill this space with a fluid-like flow. A driven oscillator is put into this form by identifying velocity as a second phase coordinate and time as a third (with $i = 1$).

A fixed (equilibrium) point with $\mathbf{f}(\mathbf{x}) = \mathbf{0}$ is asymptotically stable if all local trajectories flow into it (Figure 1). This point attractor is exemplified by the hanging state of a damped pendulum. The equilibrium of a Hamiltonian system (undamped pendulum) can be at most neutrally stable with all trajectories staying close, though not converging. A point is unstable if any single adjacent motion moves out of the neighborhood (inverted pendulum).

Figure 1. Potential well (a), and phase portrait (b), for $\ddot{x} + 0.4\dot{x} + dV(x)/dx = 0$, where $V(x) = x^4/4 + x^3/3 - x^2$, showing two asymptotically stable minima and an unstable maximum. In the enlarged focus (c), representing either minimum, we can devise a region D from which no trajectories leave the small region E, guaranteeing stability; in (d) we cannot construct a closed neighborhood around the saddle from which no trajectories leave E, proving instability.

Linear Stability

Stability analysis starts with the linearized equations describing small variations about the state. For a fixed point of a flow, stability hinges on the real parts, α_i , of the eigenvalues. Typically, the point will be hyperbolic (noncritical) with no $\alpha_i = 0$, and we then have (asymptotic) stability if and only if (iff) all $\alpha_i < 0$. Any one $\alpha_i > 0$ gives instability.

For a cycle we use an $(n - 1)$ -dimensional Poincaré mapping, $\mathbf{x}_{i+1} = \mathbf{F}(\mathbf{x}_i)$, where the cycle is a fixed point with $\mathbf{x}_{i+1} = \mathbf{x}_i$. Stability hinges on the moduli, ρ_i , of the eigenvalues. Stability of a (hyperbolic) periodic orbit requires all $\rho_i < 1$.

An unstable state, attracting in some directions, repelling in others, is a saddle. The instability index (degree of instability) is the number of $\alpha_i > 0$ (or $\rho_i > 1$). In nonlinear dissipative systems, saddles with index 1 play an important role organizing basin boundaries.

Nonlinear Stability

A conservative system has zero divergence in phase space (Liouville's theorem), like an incompressible

fluid. With dissipation, the negative divergence ensures that an ensemble of starts will shrink onto an attracting set of zero volume. Such a post-transient can be a point, periodic, quasi-periodic, or chaotic attractor. Generically, each attractor is surrounded by its own basin of attraction. All transients from a vanishingly small neighborhood move asymptotically back to it, making it asymptotically stable.

To assess how stable an attractor is against finite disturbances, we estimate the size of its basin. A brute-force method is to make computer simulations from a grid of starts; more efficient is cell-to-cell mapping (Hsu, 1980). A refined approach is to locate a governing saddle and run simulations backwards in time to trace out the boundary formed by its stable manifold (inset). Boundaries can, however, be fractal, making their detailed location impossible (McDonald et al., 1985; Thompson & Stewart, 2002). Analytical techniques, notably Lyapunov's second (direct) method (La Salle & Lefschetz, 1961), can identify contracting (trapping) regimes of guaranteed return, but they may be excessively conservative.

Local nonlinear analysis is necessary to test the Lyapunov stability of a nonhyperbolic state at which a system is about to lose its stability. An oscillator with exclusively nonlinear negative damping is, for example, linearly (non-asymptotically) stable but nonlinearly unstable. In contrast to Lyapunov's local concept, a point is globally stable if every trajectory tends to it.

Loss of Stability

When linear theory indicates a loss of stability, the nonlinear system exhibits a bifurcation. Consider first an α_i passing through zero along a path. If a real eigenvalue becomes zero, we have a saddle-node bifurcation. Typically this gives a fold, at which the path folds smoothly back at a maximum of the control parameter, μ . A saddle-node coalescence at $\mu = \mu^C$ leaves no local solution; the system jumps to a distant, unrelated attractor (Figure 2). With symmetry the saddle-node manifests itself as a pitchfork (Figure 3). Two α_i of a complex conjugate pair passing through zero give the Hopf bifurcation generating stable or unstable cycles.

A mapping loses stability when a ρ_i reaches one. If a real eigenvalue equals $+1$, we have a saddle-node bifurcation, typically a cyclic fold. If it equals -1 , we have a flip (period-doubling) bifurcation. If a complex conjugate pair penetrates the unit circle, we have the Neimark–Sacker (secondary Hopf) bifurcation.

Structural Stability

Because parameters of a physical system are never known precisely and may vary, a mathematical model should ideally have a phase portrait that is robust

Figure 2. Two phase portraits illustrating the ABC of nonlinear dynamics. Here A stands for attractor, an example of which we see in the center of (a). B stands for basin, and we see the circular basin of attraction in (a); its boundary defined by the flow into an unstable saddle point. C stands for catastrophe, conveniently used here to mean bifurcation. Under variation of a control, (a) has changed qualitatively to become the portrait (b); the central stable node has collided with the saddle in a fold bifurcation, leaving no attractor and all trajectories flowing out to infinity. (Figure reproduced with permission of John Wiley from Thompson & Stewart 2002.)

Figure 3. Stability of a rotating mass of a self-gravitating liquid is a classical problem in astrophysics, relevant to planetary evolution and the origin of satellites. It dates back to Poincaré (1899), and following the buckling studies of Euler, it gave fresh impetus to the development of stability and bifurcation theory. Stable (unstable) paths are denoted by solid (broken) lines. As the angular momentum parameter is slowly increased, the rotationally symmetric spheroids become unstable at the supercritical pitchfork at B. Emerging from B is a rising path of stable ellipsoids (with semi-axes a, b, c), which then exhibit a secondary instability at the subcritical pitchforks at C, from which unstable pear-shaped forms of “amplitude” p descend. (Figure reproduced with permission of John Wiley from Thompson, 1982.)

against small changes in the model itself. Small changes of parameters and functions should not qualitatively change the topology. A portrait having this robustness is structurally stable. Structurally unstable portraits encountered under variation of μ signal a bifurcation.

If we have m controls, μ_i , bifurcations observed under variation of one μ_i will lie in control space on surfaces of dimension $m - 1$. A bifurcation in phase-control space is structurally stable if the whole event is topologically robust. Catastrophe theory (Poston & Stewart, 1978) shows how bifurcations of equilibria that are structurally unstable under one μ_i can be made structurally stable (unfolded) by embedding in a higher-dimensional control space. The codimension is the number of μ_i needed to achieve this. An example is the symmetry-breaking imperfection needed to unfold a pitchfork into the codimension-two cusp. The resulting saddle-node locus gives the imperfection-sensitivity of elastic stability theory (Thompson & Hunt, 1973).

STANDARD MAP

The standard or Taylor–Chirikov map is a family of area-preserving maps: $z' = f(z)$ where $z = (x, y)$ is the original position and $z' = (x', y')$ the new position after application of the map, which is defined by

$$\begin{aligned}x' &= x + y - \frac{k}{2\pi} \sin(2\pi x), \\y' &= y - \frac{k}{2\pi} \sin(2\pi x).\end{aligned}\quad (1)$$

Here x is a periodic configuration variable (usually computed modulo 1), $y \in \mathbb{R}$ is the momentum variable, and the parameter k represents the strength of a nonlinear kick. This map was first proposed in 1968 by Bryan Taylor and then independently obtained by Boris Chirikov to describe the dynamics of magnetic field lines. The standard map and Hénon's area-preserving quadratic map are extensively studied paradigms for chaotic Hamiltonian dynamics.

The standard map is an “exact symplectic” map of the cylinder. Because $x'(x, y)$ is a monotone function of y for each x , it is also an example of a monotone twist map (See **Aubry–Mather theory**). Every twist map has a Lagrangian generating function, and the standard map is generated by $F(x, x') = \frac{1}{2}(x' - x)^2 + (k/4\pi^2) \cos(2\pi x)$, so that $y = -\partial F/\partial x$ and $y' = \partial F/\partial x'$. The map can also be obtained from a discrete Lagrangian variational principle as follows. Define the discrete action for any configuration sequence $\dots, x_{t-1}, x_t, x_{t+1}, \dots$ as the formal sum

$$A[\dots, x_{t-1}, x_t, x_{t+1}, \dots] = \sum_t F(x_t, x_{t+1}). \quad (2)$$

Then an orbit is a sequence that is a critical point of A . This gives the discrete Euler–Lagrange equation

$$x_{t+1} - 2x_t + x_{t-1} = -\frac{k}{2\pi} \sin(2\pi x_t). \quad (3)$$

This second difference equation is equivalent to (1) upon defining $y_t = x_t - x_{t-1}$.

The standard map is an exact or approximate description of many physical systems, including the “kicked rotor.” Consider a rigid body with moment of inertia I that is free to rotate in a horizontal plane about its center of mass. Suppose that an impulsive torque $\Gamma(\theta) = -A \sin(\theta)$ is applied to the rotor at times nT , $n \in \mathbb{Z}$. Let (θ_j, L_j) be angular position and angular momentum at time $jT - \varepsilon$ for $\varepsilon \rightarrow 0^+$. At time T later, these become $(\theta_{j+1}, L_{j+1}) = (\theta_j + (T/I)L_{j+1}, L_j + \Gamma(\theta_j))$. Scaling variables appropriately gives (1).

The standard map also describes the relativistic cyclotron and is the equilibrium condition for a chain of masses connected by harmonic springs in a periodic potential—the Frenkel–Kontorova model introduced in 1938 (Meiss, 1992). Similar maps include Chirikov's separatrix map (valid near the separatrix of a resonance), the Kepler map (describing the motion of comets under the influence of Jupiter as well as a classical hydrogen atom in a microwave field), and the Fermi map (for a ball bouncing between oscillating walls) (Lichtenberg & Leiberman, 1992). The higher-dimensional version is the Froeshlé map (See **Symplectic maps**).

Symmetries

The standard map f has a number of symmetries that lead to special dynamical behavior. To see these, it is convenient to lift the map from the cylinder to the plane by extending the angle variable x to $\mathbb{R}$.

Let $T_{m,n}(x, y) = (x + m, y + n)$ be the translation by an integer vector (m, n) . As f is periodic, its lift has a discrete translation symmetry $f \circ T_{m,0} = T_{m,0} \circ f$. More unusually, the standard map also has a discrete vertical translation symmetry $f \circ T_{0,n} = T_{0,n} \circ f$. Identifying orbits equivalent under these symmetries implies that standard map can be thought of as acting on the torus $\mathcal{T} = \{-\frac{1}{2} \leq x, y < \frac{1}{2}\}$.

The standard map also commutes with the reflection $S(x, y) = (-x, -y)$. This can be used to identify the lower half plane with the upper one and to restrict the map to the space $\mathcal{S} = \{(x, y) : -\frac{1}{2} \leq x < \frac{1}{2}, 0 \leq y \leq \frac{1}{2}\}$ identifying $(-\frac{1}{2}, y) \equiv (\frac{1}{2}, y)$ and each half of the upper and lower boundaries: $(x, 0) \equiv (-x, 0)$, $(x, \frac{1}{2}) \equiv (-x, \frac{1}{2})$. The map on the two sphere $\mathcal{S}$ is singular at the corners $(\pm \frac{1}{2}, 0)$ and $(\pm \frac{1}{2}, \frac{1}{2})$.

The standard map is also reversible; it is conjugate to its inverse $RfR^{-1} = f^{-1}$ (Lamb & Roberts, 1998). One reversor is $R_1(x, y) = (-x, y - (k/2\pi) \sin(2\pi x))$; this generates a family of reversors $R = f^n \circ R_1$. These reversors are involutions, $R^2 = id$, thus f can be written as the composition of two involutions $f = (f \circ R) \circ R$. Finally, the composition of a symmetry and a reversor is also a reversor, so that, for example, $R_2 = SR$ is also a reversor.

Symmetric orbits are invariant under a symmetry or a reversor. This is particularly interesting since symmetric orbits must have points on the fixed sets of the reversor, $\text{Fix}(R) = \{z : z = R(z)\}$, or on $\text{Fix}(fR)$. Because these fixed sets are curves, symmetric orbits are particularly easy to find. Rimmer showed that the bifurcations of symmetric orbits are special; for example, they undergo pitchfork bifurcations (See **Bifurcations**).

Dynamics

When $k = 0$, the dynamics of the standard map are integrable; the momentum y is an invariant. On each invariant circle $C_\omega^0 = \{(x, y) : y = \omega\}$, the angle after t iterates is given by $x_t = x_0 + \omega t \bmod 1$; thus, the dynamics are that of the constant rotation, $R_\omega(\theta) = \theta + \omega$, on the circle with rotation number ω . When ω is rational, every orbit on C_ω^0 is periodic; otherwise, they are quasi-periodic and densely cover the circle.

When $|k| \ll 1$, Moser's version of the KAM theorem implies that most of these invariant circles persist; that is, there is a rotational invariant circle C_ω on which the dynamics is conjugate to the rotation R_ω (See **Hamiltonian systems**). KAM theory applies to circles with Diophantine rotation number, that is,

$\omega \in \{\Omega : |n\Omega - m| > c/n^\tau; \forall m, n \in \mathbb{Z}, n \neq 0\}$ for some $\tau \geq 1$ and $c > 0$. This excludes, of course, all of the rational rotation numbers as well as intervals about each rational, but still leaves a positive measure set. While it is difficult to obtain reasonable estimates for the interval of k for which all Diophantine circles (with given c and τ) persist, in 1985 Herman showed analytically that there is at least one invariant circle when $|k| \leq 0.029$, and de la Llave & Rana (1990) used a computer-assisted proof to extend this result up to 0.91.

Some of the periodic orbits on the rational circles $C_{m/n}^0$ also persist for nonzero k . Indeed, the Poincaré–Birkhoff theorem implies that there are at least two period n orbits (with positive and negative Poincaré indices). Aubry–Mather theory implies that orbits with rotation number m/n can be found variationally; one is a global minimum of the action (2), and the other is a minimax point (a saddle of A with one downward direction). For example, when $k > 0$, $(\frac{1}{2}, 0)$ is a minimizing fixed point, and $(0, 0)$ is a minimax fixed point. The reversibility of the standard map implies that there must be symmetric periodic orbits for each $\omega = m/n$ as well. Indeed, it is observed that the minimax periodic orbits always have a point on the line $\text{Fix}(R) = \{y = 0\}$, the “dominant” symmetry line.

The minimax orbits are elliptic when k is small enough. A convenient measure of stability of a period- n orbit is Greene's residue

$$R = \frac{1}{4}(2 - \text{Tr}(M)), \quad M = \prod_{i=0}^{n-1} Df(z_i).$$

An orbit is elliptic when $0 < R < 1$. For example, the fixed point $(0, 0)$ has residue $k/4$. Perturbation theory shows that the residues of the minimizing and minimax orbits are $\mathcal{O}(k^n)$.

Each nondegenerate minimum of the action (2) is a hyperbolic orbit and has unstable and stable manifolds. For each minimizing m/n orbit, these intersect and enclose the minimax orbit, forming an island chain or resonance. The intersection of the manifolds is transverse, though the angle between them is exponentially small in k (Gelfreich & Lazutkin, 2001).

A number of island chains are easily visible in computer simulations. In the color figure (See **Standard map**: on page 8 of color plate section), we show a number of orbits of the standard map for $k = 0.6$ on the torus $\mathcal{T}$. In the figure, each of the blue curves is formed from many iterates on a rotational invariant circle like those predicted by the KAM theorem. The green orbits are secondary and tertiary circles arising from resonances.

When stable and unstable manifolds intersect transversely, some iterate of the map has a Smale horseshoe. This implies that there is, at least, a Cantor set of chaotic orbits. Umberger & Farmer (1985)

showed numerically that there is a fat fractal set on which the dynamics has a positive Lyapunov exponent. The proof of this statement is still illusive. The regions occupied by chaotic orbits appear to grow in measure as k increases. Numerically, it appears that a single initial condition densely covers each “zone of instability,” a chaotic zone bounded by invariant circles. Chaotic trajectories that were only slightly visible in the previous color figure (gold orbits near the stable and unstable manifolds of the resonances) dominate the dynamics when $k = 2.0$ (See **Standard map**: page 8 in the color plate section). At this value of k , there are no rotational invariant circles. In the figure, the gold region is filled by a single trajectory with 1.5×10^6 iterates. It appears to densely cover most of phase space, though there are still a number of secondary and tertiary islands visible.

There are also many elliptic periodic orbits that are created for nonzero k . For example, the $(0, 0)$ fixed point undergoes a period-doubling bifurcation at $k = 4$, creating a period-two orbit. More generally, when the eigenvalues of any elliptic period- n orbit are $\lambda_{\pm} = e^{\pm 2\pi i \omega}$, then new orbits are born that encircle the original orbit and have relative rotation number ω . When $\omega = m'/n'$, these correspond to a chain of nn' islands. The color figure (See **Standard Map**: page 8 in the color plate section) shows red and blue island chains that encircle the fixed point with rotation number $\frac{1}{2}$; that there are two such chains is due to the reflection symmetry S . As Birkhoff realized, the newly created elliptic orbit also will undergo similar bifurcations, so that the phase space shows a structure of islands-around-islands, ad infinitum. This structure can even exhibit self-similarity (Meiss, 1992) just like the Feigenbaum period-doubling sequence for dissipative systems.

The Last Invariant Circle

In 1968, John Greene began studying the destruction of invariant circles in the standard map. He showed that sequences of periodic orbits, namely, the minimizing and minimax m/n orbits, whose rotation numbers converge on a given irrational, can be used to determine the existence of a circle with that frequency. Suppose that ω has a continued fraction expansion $[a_0, a_1, \dots]$, $a_j \in \mathbb{Z}^+$, and let $m_j/n_j = [a_0, a_1, \dots, a_j]$ be the j th convergent of ω . Greene conjectured that when the residues of these orbits $R_j \rightarrow 0$, as $j \rightarrow \infty$, then the invariant circle C_ω exists—MacKay (1992) gives a proof of much of this.

For the standard map, it appears that each rotational invariant circle exists only up to a critical value, $k = k_{\text{cr}}(\omega)$; this graph was called the “fractal diagram” by Schmidt and Bialek in 1982. The critical k vanishes at every rational and appears to have local maxima for each noble irrational ω . Percival called a number noble if its continued fraction expansion

has a tail that is eventually all ones. By this criterion the “most irrational” number is the golden mean $\gamma = (1 + \sqrt{5})/2 = [1, 1, 1, \dots]$. Indeed for the standard map, Greene discovered that the invariant circles with rotation numbers $\gamma \pm m$, $m \in \mathbb{Z}$ appear to be the last circles destroyed (all such circles are destroyed simultaneously due the symmetries). Numerically it is known that the golden circle is destroyed at $k_{\text{cr}}(\gamma) \approx 0.971635406$.

This value is most efficiently computed by renormalization theory (MacKay, 1993). At the critical parameter for the destruction of a noble invariant circle, the phase space exhibits a self-similar structure. The geometric scaling of this self-similarity can be used to compute k_{cr} from the residues of the m_j/n_j orbits. This is more accurate than iteration methods—pioneered by Chirikov—which rely on finding an orbit that crosses the region containing the circle, and frequency methods—developed by Laskar—which rely on the irregularity of the numerically computed rotation number. While none of these methods proves that k_{cr} corresponds to the last invariant circle, “converse KAM theory” leads to a computer proof that there are no rotational circles for $k > \frac{63}{64}$ (MacKay & Percival, 1985). This is based on Birkhoff’s theorem that every rotational invariant circle is a Lipschitz graph (Meiss, 1992). The color figure (See **Standard map**: page 8 in the color plate section) shows the dynamics on the sphere S at $k_{\text{cr}}(\gamma)$. Here the golden circle (purple) is on the threshold of destruction. Also shown in the figure are 1.5×10^6 iterates of two chaotic trajectories (light blue and light green); the stable (blue) and unstable (red) manifolds of the $(m, n) = (0, 1)$, $(1, 2)$, and $(1, 3)$ orbits; and a number of orbits trapped in these island chains as well as the $(2, 5)$ and $(3, 8)$ chains.

Transport

Transport theory studies the motion of ensembles of trajectories from one region of phase space to another. When there are invariant circles separating the regions, then there is no transport. A Birkhoff “zone of instability” is an annular region bounded by, but otherwise not containing any, rotational invariant circles. Birkhoff showed there are orbits that traverse each zone of instability, and Mather (1991) extended this to show that there are orbits future and past asymptotic to the upper and lower bounding rotational invariant circles, respectively.

Aubry–Mather theory implies that for each irrational rotation number there is a minimizing trajectory that is dense on a circle or a cantor set. Percival proposed calling the latter sets “cantori.” Thus, for $k > \frac{63}{64}$, every rotational invariant circle has become a cantorus, and vertical transport between any two momentum levels occurs. The color figure (in the color plate section)

shows two such cantori (brown) with rotation numbers $(1 + \gamma)/(3 + 4\gamma)$ and $(1 + 2\gamma)/(2 + 5\gamma)$. The rate of transport is locally governed by the flux, the area that crosses a closed loop upon iteration. The flux across a cantorus or a separatrix is given by Mather's ΔW , the difference in action between the corresponding minimax and minimizing orbits (MacKay et al., 1984). Renormalization theory shows that the flux through a noble cantorus goes to zero as $(k - k_{\text{cr}})^{3.01}$; this can be very small, well beyond k_{cr} . For example in the color figure 3 (page 8 in the plate color section), the blue chaotic trajectory is bounded below by a low flux cantorus even for tens of millions of iterates. Geometrically, the flux is the area contained in a "lobe" bounded by pieces of stable and unstable manifolds. All transport occurs through lobes in two-dimensional maps (Wiggins, 1992); unfortunately, the higher-dimensional generalization is not clear.

STATE DIAGRAMS

Consider a system comprising N elements, each of which can be set at one or the other of two values. Thinking of the elements as switches, the values (positions or settings) can be defined as one of the two Boolean variables: off (0) and on (1) (Birkhoff & MacLane, 1953). Now suppose that time progresses in discrete units and the values of the switches at time t_{n+1} depend on their values at t_n . In addition to being a rather general computer model (Fowler, 2004), such a system describes certain relay and electronic switching circuits used by electrical engineers, and it provides an approximate description of biological brains (Scott, 2002), including the "nets with circles" of Warren McCulloch and Walter Pitts (McCulloch & Pitts, 1943). If the elements are placed in a geometrical pattern (e.g., a square array), one has a cellular automaton, such as John Conway's famous "Game of life" (Gardner, 1970).

To understand how the model evolves in time, it is sometimes instructive to sketch a state diagram, which displays all states of the system and shows how these states change from one time increment to the next.

In Figure 1(a), for example, this is done for a system comprising a single switch ($N = 1$), where the arrows indicate what will happen in the next increment of time. Reading from left to right, the first diagram shows a system in which the switch turns on if it is off and stays on if it is on. The second diagram shows a system that turns off if it is on and stays off if it is off. In the third diagram, the system stays off if it is off and stays on if it is on. (This corresponds to a typical wall switch.) Finally, the last diagram represents a system that turns off if it is on and turns on if it is off. (This models a "blocking oscillator" in electronic engineering.)

The number of possible state diagrams increases very rapidly with the number of elements (N) in a system. To see this, note that the number of states of the system is 2^N , and from each of these states we must choose an arrow that goes to (possibly) another state. Thus, the total number of diagrams $\mathcal{N}$ is 2^N raised to the 2^N th power, or

$$\mathcal{N} = 2^{N2^N}. \quad (1)$$

A few calculations from this formula are given in Table 1, demonstrating a growth of $\mathcal{N}$ with N , which mathematicians term "combinatorial."

For a system comprising only six switches, the total number of state diagrams is greater than 10^{110} , which in turn equals the atomic mass of the universe (the mass of the universe measured in units of the hydrogen atom) times the age of the universe in picoseconds. In his analysis of biological organisms, the physicist Walter Elsasser has called such a finite number "immense," which implies that (although the number of them is finite) it is not—and never will be—physically possible to examine all possible diagrams (Elsasser, 1998).

Figure 1. (a) The four Boolean state diagrams that can be constructed from a single switch. (b) One of the more than sixteen million state diagrams that can be constructed from three switches. Note that several arrows can converge on each state, but only one arrow leaves any one state.

N	$N = 2^{2^N}$
1	$2^2 = 4$
2	$4^4 = 256$
3	$8^8 \approx 1.7 \times 10^7$
4	$16^{16} \approx 1.8 \times 10^{19}$
5	$32^{32} \approx 1.5 \times 10^{48}$
6	$64^{64} \approx 3.9 \times 10^{115}$

Table 1. The number of state diagrams (N) that can be constructed for various numbers (N) of Boolean switches.

In Figure 1(b) is shown one of the more than sixteen million state diagrams for a system of three switches. Here we find the following behaviors.

- *Transients:* (001) $\rightarrow$ (000) $\rightarrow$ (010), (011) $\rightarrow$ (010), and (101) $\rightarrow$ (100).
- *Periodicities:* (010) $\rightarrow$ (010) and (100) $\rightarrow$ (110) $\rightarrow$ (111) $\rightarrow$ (100).
- *Disjoint dynamics:* States (000), (010), (011), and (001) are dynamically disjoint from states (100), (110), (111), and (101).

The shortest transient or period is a single time unit, whereas the longest is 2^N time units, but this is unlikely for larger values of N .

Consider how the number of state diagrams depends on the way that the state of a system in the next time increment is computed. If each switch responds to the present positions of all N switches (including itself), there are

$$2^{2^N}$$

possible Boolean functions that can perform the computations. In the most general case, any one of the N switches can be assigned one of these Boolean functions. Thus, the number of possible diagrams is equal to

$$(2^{2^N})^N = 2^{N2^N},$$

just as in Equation (1). In choosing the arrows for a particular diagram—as in Figure 1(b)—one defines a particular Boolean function.

When state diagrams are used to model biological brains, we may wish to limit the computations to threshold functions rather than Boolean functions. The total number of threshold functions of n inputs is

$$2^{kn^2},$$

where k lies between $\frac{1}{2}$ and 1 (Yajima et al., 1968). In a brain model, furthermore, it is unrealistic to assume that each neuron receives inputs from all other neurons. If each of N neurons receives inputs from n neurons, then the total number of state diagrams is

$$N_{th} \geq (2^{n^2/2})^N = 2^{n^2 N/2}. \tag{2}$$

Taking $N = 10^{10}$ as a conservative estimate for the number of neurons in the human neocortex and $n = 10^4$ as an estimate for the number of synaptic inputs to each neuron, implies that the number of possible brains is about $10^{10^{17}}$.

STEREOSCOPIC VISION AND BINOCULAR RIVALRY

Most vertebrate predators, including humans, have their two eyes positioned in the front of the head

Figure 1. (a) The geometry of stereopsis. (b) The simplest two line stereogram.

looking forward. In contrast, most prey species, such as rabbits, have eyes positioned on the sides of the head. This confers on prey almost panoramic vision, thus enabling them to see predators creeping up behind them. In contrast, predators receive two slightly different views of the scene in front of them due to the horizontal offset between the two eyes (approximately 6.7 cm in humans), which confers depth information. Stereoscopic vision may be defined as the perception of depth that arises when the brain compares the images falling on the two retinas. Indeed, there are neurons in the visual cortex that receive stimulation from both eyes and consequently are sensitive to the depth of lines and contours in the world.

The geometry of stereopsis is illustrated in Figure 1a, which provides a horizontal view of two eyes viewing a scene containing two vertical rods at different depths relative to the eyes. As shown by the dashed sight lines, the retinal images of these two lines will be closer together in one eye's view than in the other. Figure 1b contains a simple two line stereogram, namely a pair of views, one for each eye, with vertical lines closer together in one view than in the other. If the viewer can either cross or diverge their eyes so that each eye fixates a different one of these views, the percept will be one in which one line lies closer to the viewer than the other line. (It should be noted that several percent of humans lack stereoscopic ability, usually due to amblyopia or "lazy eye" during early childhood.) Rather than requiring viewers to cross or diverge their eyes, laboratory research into stereopsis utilizes some version of a stereoscope, which was

Figure 2. Random dot stereogram.

invented by Charles Wheatstone in 1838. A stereoscope utilizes either prisms or mirrors in front of each eye to optically diverge the views so that each eye views a different visual stimulus. Indeed, stereoscopes and stereoscopic photographs were a Victorian fascination, and many excellent stereoscopes may still be found in antique shops.

The two line stereogram in Figure 1b is the simplest possible, as two objects are the minimum for which different depths can be defined. A much more complex example is the random dot stereogram (RDS), which was developed by Bela Julesz (1971) as a tool for the study of stereopsis. To make an RDS, a computer first generates a completely random pattern of black and white dots (little squares), such as that depicted in Figure 2. This will be the stimulus for one eye. An exact copy of this is then made as the basis for the other eye's view. To generate a stimulus for depth, a rectangular (or other shaped) region of dots in the middle of this second random pattern is now shifted horizontally left or right by a distance of several dots. The space vacated by shifting this rectangular region is then filled in with random black and white dots. When each eye views one of the two random dot patterns in an RDS, the brain extracts depth information and produces a percept of a rectangular region of random dots floating in depth in front of (or behind, depending on which eye views which half of the stereogram) a random dot background. Readers who can converge or diverge their eyes while viewing Figure 2 can experience this.

Neural Basis of Stereopsis

Information originating in the two retinas remains segregated until it reaches primary visual cortex at the back of the brain. In the cortex, many individual neurons respond best when they are stimulated through both eyes at once. However, each cortical neuron receives stimulation only from a very small area on each retina, which is known as a "receptive field." If one imagines there being a coordinate system affixed to each retina with the center of the retina (the fovea) being the origin, then each cortical cell receives information from a pair of receptive fields, one from each retina, whose coordinates may be the same or different. If a cortical neuron receives stimulation from receptive fields with

the same relative coordinates in each retina, it will be sensitive to lines and edges that lie in the plane on which the eyes are converged. Therefore, such a neuron will be sensitive to objects with zero depth relative to fixation. Other neurons, however, have their receptive fields at different points on the two retinas. For most of these cells, this means that the receptive field in one eye is shifted a short distance horizontally left or right relative to its receptive field in the other eye. Such a difference in receptive field coordinates on the two retinas is termed a horizontal disparity. Neurons with a particular horizontal disparity will respond to objects at a particular depth relative to the fixation plane. For example, if a cortical neuron has its receptive field in the left eye shifted left relative to that in the right eye, its disparity will correspond to lines and edges nearer than fixation. Conversely, a neuron with a left eye receptive field shifted to the right relative to the other eye will be sensitive to disparities corresponding to lines and edges farther away than the plane of fixation. Thus, different cortical neurons, in virtue of the relative placement of their two retinal receptive fields, signal the location of lines and edges in three-dimensional space, including their depth relative to the fixation plane. Although only horizontal disparities are discussed here, vertical disparities are now known to play a role in stereopsis as well, and details can be found in Howard & Rogers (2002).

The RDS demonstrates dramatically the computational problems confronted by cortical neurons in comparing the two retinal images to extract depth information. To make the point, consider a single black dot in one horizontal line of the pattern in one eye's view. The corresponding horizontal line of dots in the other eye's view will contain roughly 50% black dots, any one of which might be the appropriate match for the black dot in question. Thus, the problem has an extremely large number of potential depth solutions, only one of which is actually perceived. In other words, the existence of neurons sensitive to different disparities and, therefore, different depths only represents the initial part of the solution to the problem of extracting depth information from two retinal images.

The types of interactions among disparity-tuned cortical neurons that must be involved in the extraction of accurate depth information may be appreciated by reconsidering the simple two line stereogram in Figure 1. As shown by the dashed lines in Figure 1a, sight lines from the two eyes intersect not only at the locations of the two targets (black circles) but also at two other points in depth (open circles). These are known as "false targets," and neural interactions in the cortex are required to eliminate them. The types of interactions believed to occur include facilitation between neurons tuned to similar disparities in neighboring regions plus inhibition between neurons tuned to very different disparities at adjacent points. Examination of Figure

Figure 3. Stereogram illustrating binocular rivalry. Try viewing and perceiving both images simultaneously.

1a shows that if the neurons tuned to the disparities or depths represented by the black circles were mutually excitatory, whereas both of these inhibited neurons tuned to the much more extreme disparities indicated by the open circles, the neurons representing the black circles would win the competition and suppress the responses to the false targets. Many variations on this theme of facilitation between neurons tuned to similar disparities and inhibition between neurons tuned to radically different disparities have been proposed, and these have been summarized elsewhere (Blake & Wilson, 1991). Such interactions may be conceptualized as implementing an evolutionary constraint that most real world objects are bounded by surfaces that vary smoothly in depth except at their edges.

Binocular Rivalry

The preceding discussion assumes that the two eyes are looking ahead and viewing the same scene, albeit from slightly different viewpoints that give rise to disparities. In the laboratory, however, it is possible to generate stereograms that present radically different views to the two eyes. A simple example of this is depicted in Figure 3, where one eye is presented with horizontal lines, while the other is presented with vertical lines. Readers who can converge or diverge their eyes will discover that these lines cannot be fused to produce a depth percept. Rather, one perceives an alternation between horizontal and vertical lines such that the two are almost never seen at the same point at the same time. This perceptual alternation, which occurs at a rate of about one alternation every 2–4 s, is known as binocular rivalry. Rivalry results when the two eyes view images that could not have arisen from a real three-dimensional world in the absence of mirrors or other optical devices. It appears, therefore, that rivalry must reflect neural interactions that evolved to process depth information but that default into a perceptual oscillation when the depth task is impossible.

The neural basis of binocular rivalry requires two components. First, the different groups of rivaling neurons responding to orthogonal stimuli must be strongly and mutually inhibitory. This guarantees that only one set of these neurons can be active at any given

place and time. The second ingredient is fatigue or self-adaptation. Self-adaptation, which is well documented among excitatory cortical neurons, causes neurons that are firing rapidly to slowly decrease their response rate over the course of a second or more. As they adapt, their ability to inhibit other neurons weakens. Eventually, these previously inhibited neurons overcome the inhibition and begin to respond, and they then inhibit the adapted neurons so that the percept switches. This neural mechanism has been developed into nonlinear dynamical models that accurately explain many aspects of binocular rivalry (Wilson, 2004).

A further aspect of binocular rivalry is that the reversals are not precisely periodic. Scientists have measured the duration of intervals during which the pattern presented to one eye is visible (e.g., the vertical stripes in Figure 3). The results are well described by a gamma distribution in which both short and long intervals recur in a seemingly random sequence. Recent research using neural network modeling suggests that this gamma distribution results from chaotic dynamics among cortical neurons (see Wilson, 2004).

The final and most important question concerning binocular rivalry is how the inhibitory neural interactions underlying rivalry change their role when stimuli permitting depth perception are viewed. This remains unanswered, but it is at least clear from the discussion of depth perception that inhibition is a necessary neural component. Perhaps, future research will show that the inhibition involved in elimination of false targets during depth perception is related to the inhibition causing perceptual alternations in binocular rivalry.

STOCHASTIC ANALYSIS OF NEURAL SYSTEMS

Oscillatory activity abounds in the central nervous systems of animals and humans (Freeman, 1975; Steriade et al., 1990). Single neurons may act as oscillators by rhythmically generating action potentials or bursts. Central pattern generators (Cohen et al., 1988) are networks of neurons located in the spinal cord and the brain stem, which produce oscillatory activity intrinsically (Sherrington, 1947; von Holst, 1954; Cohen et al., 1988). Central pattern generators are essential for repetitive motor behavior like walking, running, flying, swimming, and chewing (Sherrington, 1947; von Holst, 1954; Cohen et al., 1988). Phase synchronization (PS) between different central pattern generators is the mechanism that controls the different types of locomotion such as walk, trot, or gallop (von Holst, 1954; Cohen et al., 1988).

In the cortex, the well-coordinated action of neural oscillations is indispensable to physiological information processing (Freeman, 1975; Steriade et al., 1990; Haken, 1996). In-phase synchronization might be one aspect of such processes (Singer & Gray, 1995).

In several neurological diseases, brain function is severely perturbed by pathologically enhanced synchronization. Resting tremor in Parkinson's disease (PD) appears to be caused by a cluster of neurons located in the thalamus and the basal ganglia, which fires synchronously at a frequency similar to that of the tremor (3–6 Hz). While under physiological conditions these neurons fire incoherently (Nini et al., 1995); in patients with PD, this cluster acts like a pacemaker and activates cortical areas, which causes the peripheral shaking.

In patients with advanced Parkinson's disease or with essential tremors that do not respond to drug therapy, depth electrodes are chronically implanted in target areas like the thalamic ventralis intermedius nucleus or the subthalamic nucleus (Benabid et al., 1991). Electrical deep brain stimulation (DBS) is performed by administering a permanent high-frequency (> 100 Hz) periodic pulse train via the depth electrodes. DBS suppresses the activity of the pacemaker-like cluster, which, in turn, suppresses the peripheral tremor (Benabid et al., 1991). DBS has been developed empirically, mainly based on observations during stereotaxic neurosurgery. The advent of nonlinear dynamics and statistical physics in the field of clinically oriented neuroscience has led to an improvement of data analysis as well as a model-based development of stimulation techniques.

Stochastic Synchronization

Phase synchronization is a type of synchronization where two oscillators adjust their phases, while their amplitudes need not be correlated. Phase

Figure 1. 1:2 phase difference $\theta_{1,2}$ (a) and its cyclic version $\varphi_{1,2}$ (b) from Equation (1) between the activity of the right flexor muscle of a patient with Parkinsonian resting tremor and the magnetic field measured above the corresponding left sensorimotor cortex. Corresponding distribution of $\varphi_{1,2}$ (c). (Adapted from Tass et al., 1998).

synchronization is observed in many physical, chemical, and neural systems (von Holst, 1954; Haken, 1996; Tass et al., 1998; Pikovsky et al., 2001; Tass et al., 2003). As neural systems are noisy, it is convenient to use the general concept of PS, which is valid in noisy periodic oscillators as well as in chaotic oscillators (Pikovsky et al., 2001).

To study $n:m$ phase synchronization (PS) we introduce the $n:m$ phase difference $\theta_{n,m}$ and the cyclic $n:m$ phase difference $\varphi_{n,m}$ with

$$\theta_{n,m}(t) = \frac{n\phi_1(t) - m\phi_2(t)}{2\pi},$$

$$\varphi_{n,m}(t) = \frac{n\phi_1(t) - m\phi_2(t)}{2\pi} \bmod 1, \quad (1)$$

where ϕ_1 and ϕ_2 are the phases of the two oscillators. The time course of $\theta_{n,m}$ typically exhibits horizontal periods intersected by 2π jumps (Figure 1a), that vanish when the coupling is sufficiently strong compared to the noise. By $n:m$ PS is meant that the two oscillators maintain a stable relationship of $\varphi_{n,m}$ in a statistical sense (Figure 1b), and thus it is characterized by the appearance of one or more distinct peaks in the distribution of $\varphi_{n,m}$ (Figure 1c). Absence of $n:m$ PS corresponds to a uniform distribution of $\varphi_{n,m}$, whereas perfect $n:m$ PS is related to a Dirac-type distribution of $\varphi_{n,m}$. To quantify the strength of $n:m$ PS, the actual distribution is compared to a uniform distribution with synchronization indices that are based on the Shannon entropy or the Fourier transformation (Tass et al., 1998; Pikovsky et al., 2001). The phase of an oscillatory signal is determined with the Hilbert transform or the wavelet transform (Tass et al., 1998; Pikovsky et al., 2001). Already by the 1930s, PS was studied in coordinated movements using a similar, Poincaré-like approach, but limited phase estimation (von Holst, 1954).

In Parkinsonian patients with resting tremor, a 1:2 PS was found between the activity of the shaking muscles and brain areas such as the sensorimotor cortex and premotor areas (Tass et al., 1998) (Figure 1). The dominant frequency of the activity in the brain areas is approximately twice as large as that of the peripheral tremor.

Compared to PS analysis, the cross coherence method cannot distinguish between PS and amplitude modulation as well as between PS and simple linear superposition. Furthermore, cross coherence is not appropriate for the detection of $n:m$ PS with $n/m \neq 1$ (Tass et al., 1998; Pikovsky et al., 2001, 2003).

Stochastic Phase Resetting

In both single neurons and neural populations, the effect of a stimulus depends on the phase of the neural oscillation at which the stimulus is administered. To study phase-dependent effects of pulsing stimuli on neural populations and, in particular, to analyze desynchronizing effects of such stimuli, the concept of phase resetting (Winfree, 1980) has been extended to populations of non-interacting and interacting oscillators in the presence of random forces (Tass, 1999). The single neuron is modeled by a phase oscillator (Kuramoto, 1984). The dynamics of a cluster of N interacting phase oscillators subject to a stimulus S and to random forces F_j is governed by

$$\dot{\psi}_j = \omega_j + \frac{1}{N} \sum_{k=1}^N \Gamma(\psi_j - \psi_k) + X(t) S(\psi_j) + F_j(t), \quad (2)$$

where ψ_j is the phase of the j th phase oscillator, Γ is a 2π -periodic global coupling, and S is a 2π -periodic, time-independent function modeling the stimulus, where $X(t)=1$ during stimulation and $X(t)=0$ without stimulation (Tass, 1999). The random forces $F_j(t)$ are modeled by Gaussian white noise fulfilling $\langle F_j(t) \rangle = 0$, $\langle F_j(t) F_k(t') \rangle = D \delta_{jk} \delta(t - t')$ with constant noise amplitude D .

Via the Fokker-Planck equation, one obtains an evolution equation for the average number density $n(\psi, t) = \int_0^{2\pi} \dots \int_0^{2\pi} d\psi_1 \dots d\psi_N \tilde{n}(\Psi; \psi) f(\psi; t)$, where $f(\psi, t)$ is the probability density with $\Psi = (\psi_1, \dots, \psi_N)$ and $\tilde{n}(\Psi; \psi) = N^{-1} \sum_{j=1}^N \delta(\psi - \psi_j)$. $n(\psi, t)$ tells us how many oscillators most probably have phase ψ at time t . Detailed analytical studies of

that equation were performed for $X=0$ (Kuramoto, 1984; Tass, 1999), whereas the transient stimulation-induced dynamics was analyzed numerically, mainly for the case when all oscillators have the same eigenfrequency (Tass, 1999). Since the single model neuron fires whenever its phase equals 0 (modulo 2π) the average number density of firing neurons is given by the firing density

$$p(t) = n(0, t). \tag{3}$$

It is possible to desynchronize a synchronized cluster of oscillators with a single pulse of the right intensity and duration. To this end, however, the pulse has to hit the cluster in a vulnerable phase range, which corresponds to only a small fraction (5% or even less) of a period of the oscillation. To compound matters, different stimulation parameters have to be used to desynchronize a cluster that is not in its fully synchronized state (Tass, 1999). Hence, complex stimulation techniques have been developed that make it possible to effectively desynchronize a cluster of phase oscillators independently of the cluster's dynamical state at the beginning of the stimulation (Tass, 2002). These methods share one particular feature: the stimulus consists of two qualitatively different stimuli. The first stimulus is stronger and resets (restarts) the cluster, whereas the second, weaker stimulus is a single pulse that is administered after a constant time delay and desynchronizes by hitting the cluster in a vulnerable state. The goal of the reset is to control the dynamics of the cluster by restarting the cluster in a stereotypical way. The reset may be achieved by means of a strong single pulse, a high-frequency pulse train (HFPT) (with a pulse rate 20 times larger than the mean eigenfrequency $\bar{\omega}$) or a low-frequency pulse train (LFPT) (with a pulse rate similar to $\bar{\omega}$) (Tass, 2002). A strong pulse and an HFPT cause a hard (abrupt) reset within less than one period, whereas an LFPT causes a soft (slow) reset, where in the course of an entrainment the influence of the initial dynamic state fades away.

Since the desynchronizing effect of these stimulation techniques does not depend on the initial dynamical state of the neural population, resynchronization can effectively be blocked by administering a desynchronizing stimulus whenever the population tends to resynchronize (Figure 2a). In contrast, high-frequency stimulation not combined with a desynchronizing single pulse causes only a suppression of the firing during stimulation but no desynchronization (Figure 2b). After a simple HFPT, the extent of synchronization is particularly high, and the cluster restarts in a rebound-like manner.

Transient stimulus-induced responses of coupled neural oscillators are a key approach not only for manipulating synchronization processes, but also for studying neural information processing in basic

Figure 2. (a) Firing density p from Equation (3) of a neural population stimulated with two subsequent identical composite stimuli consisting of a high-frequency pulse train followed by a single pulse. (b) Two successively administered identical high-frequency pulse trains with parameters as in (a) but without following single pulses. Begin and end of a single pulse are indicated with vertical lines connected by a shaded region ((a) and (b) from Tass, 2001). CT distributions from Equation (5) of ϕ_1 (c) and ϕ_2 (d) show that the post-stimulus responses of each oscillator split into two antiphase ensembles (0 is black and maximal values are white). Begin (at $t=0$) and end of stimulation are indicated by vertical lines. ((c) and (d) from Tass, 2003).

research as well as in diagnosis (Dawson, 1954; Steriade et al., 1990). To improve the signal-to-noise ratio, one typically averages across an ensemble of responses to reveal what is supposed to be the actual response to a stimulus (Dawson, 1954). But noise inherent in the neural dynamics makes coupled neural oscillators react to a stimulus in more than one way, which may be essential for sensory short-term adaptation (Tass, 2003). In this case, averaging causes severe artifacts.

For illustration we consider Equation (2) for two coupled oscillators ($N=2$) undergoing an antiphase reset caused by stimuli $S_1(\psi_1)=I \cos(\psi_1)$ and $S_2(\psi_2)=I \cos(\psi_2 + \pi)$. We use the normalized cyclic phases

$$\phi_j(t) = \frac{\psi_j(t)}{2\pi} \bmod 1 \quad (j = 1, 2) \tag{4}$$

and the normalized cyclic $n:m$ phase difference $\varphi_{n,m}$ from Equation (1). To detect whether, in an ensemble of responses, there are epochs during which the phases ϕ_j and/or the phase difference $\varphi_{n,m}$ display, a stereotypically, tightly stimulus-locked time course; the stimuli S_1 and S_2 are simultaneously administered at l random times $\tau_1, \tau_2, \dots, \tau_l$. Time-dependent

cross-trial (CT) distributions of ϕ_j and $\varphi_{n,m}$ are calculated across trials for each time t relative to stimulus onset with

$$\{\phi_j(t + \tau_k)\}_{k=1,\dots,l}, \{\varphi_{n,m}(t + \tau_k)\}_{k=1,\dots,l}. \quad (5)$$

The time course of ϕ_j and $\varphi_{n,m}$ is perfectly stimulus-locked at time t if the corresponding CT distributions are Dirac-type distributions, whereas these distributions are uniform if ϕ_j and $\varphi_{n,m}$ are not stimulus-locked at all at time t . The extent of stimulus locking is quantified for each time t with indices characterizing the corresponding CT distributions with Shannon entropy or Fourier transformation (Tass, 1999, 2003). In this way, it is possible to detect stimulus-locked transient synchronization/desynchronization ($\varphi_{n,m}$) as well as transient cross-trial response clustering (ϕ_j). The latter is illustrated in Figures 2c and d, where the pre-stimulus CT distribution of ϕ_j is nearly uniform because of the randomized stimulus application. In all of the $l=200$ trials, the stimuli S_1 and S_2 reset the oscillators to the phases $\phi_1^{\text{res}} \approx 0.36$ and $\phi_2^{\text{res}} = \phi_1^{\text{res}} + 0.5$, so that Dirac-like CT distributions evolve. Each oscillator reacts in two qualitatively different ways: The ensemble of post-stimulus responses starts at ϕ_j^{res} and splits into two antiphase ensembles, so that two antiphase peaks of the corresponding CT distribution emerge. The mechanism that induces cross-trial response clustering is a stochastic resonance (Tass, 2003).

Coordinated transient responses of neural oscillators such as antiphase cross-trial response clustering typically escape detection with standard methods like cross-trial averaging (Tass, 2003).

Deep Brain Stimulation Techniques

Permanent high-frequency DBS is an unphysiological type of stimulation, which in a number of patients leads to side effects like dysarthria and psychiatric symptoms. Furthermore, the therapeutic effect of DBS may vanish in the course of the treatment, possibly due to adaptation.

Demand-controlled DBS with the stimulation techniques explained in the former section has been suggested as an alternative and milder therapeutic approach (Tass, 2002). Instead of simply suppressing the neural firing of the pacemaker-like cluster, these novel stimulation techniques aim at desynchronizing the pacemaker's pathologically synchronized firing in a demand-controlled way (Tass, 2002). For this, either the depth electrode or an epicortical electrode measures the feedback signal, that is, the local field potential of the pacemaker population or the electrical activity of a cortical area that is strongly coupled to it. A desynchronizing stimulus is administered only whenever the pacemaker-like cluster becomes synchronized

(Figure 2a). Repeated administration of desynchronizing stimuli may effectively maintain an uncorrelated firing. Demand-controlled DBS should, in principle, be less aggressive to the brain tissue stimulated and is currently evaluated for clinical use.

STOCHASTIC PROCESSES

Complex processes in physics, chemistry, biology, engineering, and finance often exhibit uncertainties, fluctuations, or noises in their structures as a rule rather than as an exception. It is known that low-dimensional nonlinear dynamical systems can exhibit chaotic phenomena that appear random in nature. Nevertheless, stochastic processes involve an unmanageably large number of variables and their temporal fractal dimensions approach infinity. To interpret, analyze, model, and simulate these noises, several stochastic algorithms developed in the last century yield not only the structure or pattern of these processes, but also the statistical characteristics of the underlying uncertainties that the conventional deterministic models cannot offer.

Analysis of a stochastic process usually starts with the assumption of a Markov property. A Markov process, $X(t)$, is a stochastic process with the property that, given the value of $X(t = t_r)$, the values of $X(t = t_s)$ for $t_s > t_r$ are not influenced by the values of $X(t = t_q)$ for $t_q < t_r$. Depending on the nature of the process and the method of analysis, the random variable, $X(t)$, may assume continuous values or only discrete values. Moreover, the random variable can be analyzed with a continuous or a discrete time scale.

Algorithms have been developed for analyzing two distinct types of noise, internal and external. Internal noise is caused by the fact that the system itself consists of discrete particles and many variables associated with the particles are ignored; it is inherent in the very mechanism by which the process evolves. Small discrete systems governed by a large number of variables often exhibit notable internal fluctuations. The energy state of an electron in a molecule, the spread of an epidemic within a population, the mutation of a gene, and diffusion of a molecule into a medium cannot be predicted precisely due to their inherent complexities; thus, these processes exert internal fluctuations. The discrete state, continuous-time stochastic processes can be analyzed by the master equation in the following general form (Oppenheim et al., 1977; Gardiner, 1985; van Kampen, 2001):

$$\frac{dp_n(t)}{dt} = \sum_{n'} \{W_{nn'} p_{n'}(t) - W_{n'n} p_n(t)\}, \quad (1)$$

where $p_n(t)$ denotes the probability of the system to be in state n at time t , and $W_{nn'}$ the transition probability per unit time from state n' to state n . The master

equation is a gain-loss equation for the probabilities of the separate state n . The first term is the gain of state n due to transitions from other states n' , and the second term is the loss due to transition from n into other states. For a system involving a set of random variables or a random vector, n is a vector and $W_{n'n}$ is a matrix.

When all elements of the transition intensity functions $W_{n'n}$ are either constant or linear functions of n , Equation (1) is considered a linear master equation; otherwise, it is considered nonlinear. Simple linear master equations such as the Poisson equation and birth and death processes can be solved by induction (see, e.g., Karlin & Taylor, 1975). For processes involving large numbers of random variables, full solutions of their joint probability distribution function are usually difficult, if not impossible, and it often suffices to determine only the first and second moments of the resultant probability distribution. These moments can be found by taking the averages of the master equations or by the method of joint probability generating function (Karlin & Taylor, 1975, 1981; Chiang, 1980). For nonlinear master equations, solutions can be approximated by resorting to the system-size expansion, a rational linearization approximation technique based on the power-series expansion (van Kampen, 1976, 2001). The system size, Ω , has been proposed as an expansion parameter because it measures the relative importance of the noises. For a linear system, fluctuations or variances are of the order of $\Omega^{1/2}$ in a collection of Ω entities. As a result, their effect on the macroscopic properties is of the order of $\Omega^{1/2}$. It is expected that the joint probability for the nonlinear system, $p_n(t)$, will have a sharp maximum around the macroscopic value with a noise of width of the order of $\Omega^{1/2}$. Thus, when the higher-order moments are ignored, the approximated joint probability becomes a time-dependent Gaussian distribution. The technique gives rise to the deterministic macroscopic equations and the equations of noises for the master equation; the latter is a set of linear Fokker–Planck equations whose characteristics and solutions will be discussed below.

For the interpretation of its relation with other stochastic algorithms, the master equation has been expressed in terms of a continuous random variable $Y(t)$ with its realization $y(t)$

$$\frac{\partial P(y, t)}{\partial t} = \int \{W(y | y') P(y', t) - W(y' | y) P(y, t)\} dy'. \quad (2)$$

Taylor expansion of the above master equation yields the Kramers–Moyal expansion

$$\frac{\partial P(y, t)}{\partial t} = \sum_{v=1}^{\infty} \frac{(-1)^v}{v!} \left(\frac{\partial}{\partial y} \right)^v \{a_v(y) P(y, t)\}, \quad (3)$$

where $a_v(y)$ denotes the jump moments:

$$a_v(y) = \int_{-\infty}^{\infty} r^v W(y, r) dr \quad (4)$$

and

$$W(y | y') = W(y', r), \quad r = y - y'. \quad (5)$$

A particular important class of continuous Markov processes is that for which $a_v(y) = 0$ for $v \geq 3$ in Equation (3). It is called the Fokker–Planck equation or the diffusion process (Risken, 1996):

$$\begin{aligned} \frac{\partial P(y, t)}{\partial t} &= -\frac{\partial}{\partial y} a_1(y) P(y, t) \\ &+ \frac{1}{2} \frac{\partial^2}{\partial y^2} a_2(y) P(y, t), \end{aligned} \quad (6)$$

where a_1 and $a_2/2$ are called the drift and diffusion coefficients, respectively. Thus, the Fokker–Planck equation is a truncated master equation. If a_1 is a linear function of y and a_2 is constant, Equation (6) is called a linear Fokker–Planck equation, a linearity definition consistent with that of the master equation. Linear Fokker–Planck equations have been used by Rayleigh, Einstein, Smoluchowski, and Fokker for special cases. Taking the moments of Equation (6) yields the equations governing the mean trajectory and the noise around the mean. The solutions of these equations are sufficient in the construction of the macroscopic trajectory and its time-dependent Gaussian noise. An Ornstein–Uhlenbeck process is characterized by the jump coefficients, $a_1(y) = -ky$, and $a_2(y) = D$ where the constants satisfy $k > 0$ and $D \geq 0$ (Gillespie, 1992). For an Ornstein–Uhlenbeck process with the initial condition $P(y, t=0) = \delta(y - y_0)$, where δ denotes Dirac's delta function, its evolution of the probability distribution function can be written as

$$\begin{aligned} P(y, t) &= \frac{1}{[\pi \frac{D}{k} (1 - \exp[-2kt])]^{0.5}} \\ &\times \exp \left\{ -\frac{(y - y_0 \exp[-2kt])^2}{\frac{D}{k} (1 - \exp[-2kt])} \right\}. \end{aligned} \quad (7)$$

The evolution of an Ornstein–Uhlenbeck process and its statistical features are illustrated in Figure 1.

A discrete state, discrete time stochastic process can be designated by X_i , where $X_i = X(t = t_i)$ and $i = 0, 1, 2, \dots$. X_i is called a Markov chain if it follows the Markov property. Examples of these processes include a random walk on a line, the number of persons in a waiting line at 1 minute intervals, and the number of catalyst particles of different sizes during attrition. The propagation of a Markov chain can be expressed in the following matrix form (Taylor & Karlin, 1998):

$$p(X_n) = p(X_0) P^n, \quad (8)$$

Figure 1. The evolution of an Ornstein–Uhlenbeck process, and its statistical features. The process starts with a given deterministic, initial condition, $P(y, t=0) = \delta(y - y_0)$, and its fluctuations grow over time and eventually stabilize. The plot is drawn for $y_0 = 20$, $k = 20$, and $D = 1$. The solid line on the (y, t) -plane, $y(t) = y_0 \exp(kt)$, denotes the macroscopic trajectory and its limiting distribution when $t \rightarrow \infty$ depicts the Brownian motion.

where $p(X_k)$ is a row vector representing the probability distribution at t_k and P is the one-step transition probability matrix with the following elements:

$$P_{ij} \equiv Pr\{X_{k+1} = j | X_k = i\}. \quad (9)$$

Equation (9) suggests that the probability distribution at a given time t_k can be estimated by successive matrix multiplication.

External noises are the fluctuations created in an otherwise deterministic system by the application of an external random force, whose stochastic properties are supposed to be known. The displacement of a mass attached to a spring with a fluctuating external force, an animal population under the influence of a fluctuating environment, the response of an electronic circuit equipped with a noise generator, the random loading of a bridge, and the yield from a chemical reactor with a fluctuating feed rate are examples of external noises. The Langevin approach is widely used for the purpose of finding the effect of noise in macroscopically known systems. The noise is introduced by adding a random term, $L(t)$, to the deterministic equation (Karlin & Taylor, 1981; van Kampen, 2001; Øksendal, 2003)

$$\frac{dy}{dt} = A(y) + C(y)L(t), \quad (10)$$

where $A(y)$ denotes the macroscopic characteristics of the system and $C(y)$ characterizes the interaction of the noise and the system. When $A(y)$ is a linear function of y and $C(y)$ a constant, Equation (10) is called a linear Langevin equation. When $A(y)$ is a nonlinear function of y and $C(y)$ a constant, Equation (10) is called a quasilinear Langevin equation. When $C(y)$ is a function of y , Equation (10) is called a nonlinear Langevin

equation. These linearity definitions are consistent with those for the master and the Fokker–Planck equations after transformations. This consistency is important because some difficulties emerge during the integration of a Langevin equation that yields the Fokker–Planck equation (van Kampen, 2001). The treatment of the discontinuous stochastic noise, $L(t)$, is the source of the complexity. The added external noise, or the Langevin force, $L(t)$, is irregular and unpredictable, but its averaged properties over an ensemble of similar systems are simple. White noise is a commonly adopted simplification, which satisfies two averaged properties. Its ensemble has zero; that is,

$$E[L(t)] = 0. \quad (11)$$

Moreover, the individual noise takes place instantaneously with strength $\sqrt{\Gamma}$, and two successive noises arrive uncorrelated; that is,

$$E[L(t)L(t')] = \Gamma\delta(t - t'). \quad (12)$$

The spectral distribution of white noise, or the Fourier transform of Equation (12), is independent of the frequency ω . If the noise $L(t)$ is not δ correlated, the spectral density depends on the frequency and one uses the term *colored noise*.

Taking the first and second moments of Δy associated with a Langevin equation yields the jump moments of the Fokker–Planck equation. For a linear Langevin equation with $C(y)=1$, the averaging process give rise to a linear Fokker–Planck equation (see, e.g., van Kampen, 2001)

$$\frac{\partial P(y, t)}{\partial t} = -\frac{\partial}{\partial y} A(y)P(y, t) + \frac{\Gamma}{2} \frac{\partial^2}{\partial y^2} P(y, t), \quad (13)$$

and it represents an Ornstein–Uhlenbeck process. For a quasilinear Langevin equation, the process gives rise to an expression identical to Equation (13). Nevertheless, the nonlinear nature of $A(y)$ suggests its Fokker–Planck equation is also nonlinear. Analytical solutions of the nonlinear Fokker–Planck equation are discussed by Risken (1996) and Grasman and van Herwaarden (1999).

Due to the discontinuous nature of $L(t)$, integrating $C(t)L(t)$ of a nonlinear Langevin equation in the averaging process, however, results in two different interpretations. If the averaged value of $C(y)$ during $(t, t + \Delta t)$ is used, the averaging process yields

$$\begin{aligned} \frac{\partial P(y, t)}{\partial t} = & -\frac{\partial}{\partial y} [A(y)P(y, t)] \\ & + \frac{\Gamma}{2} \frac{\partial}{\partial y} \left[C(y) \frac{\partial}{\partial y} [C(y)P(y, t)] \right] \end{aligned} \quad (14)$$

and the integration procedure is called the Stratonovich calculus. If the value of $C(y)$ before the arrival of the delta peak during $(t, t + \Delta t)$ is used, the averaging

process yields

$$\begin{aligned} \frac{\partial P(y, t)}{\partial t} = & -\frac{\partial}{\partial y} [A(y)P(y, t)] \\ & + \frac{\Gamma}{2} \frac{\partial^2}{\partial y^2} [C^2(y)P(y, t)] \end{aligned} \quad (15)$$

and the integration procedure is called the Ito calculus. For practical processes experiencing external noise, the noise $L(t)$ is never infinitely sharp, and it lasts for a finite period of time; this consideration suggests that the Stratonovich interpretation is appropriate (van Kampen, 2001).

STRING THEORY

String theories (Green et al., 1987; Davies & Brown, 1988; Polchinski, 1998; Gauntlett, 1998; Kaku, 1999) were developed in the 1980s and 1990s in the hope of finding a unified description of all forces in nature. The aim is to combine electroweak, strong, and gravitational interactions into one consistent theory. The basic idea is that subatomic particles are not point-like but one-dimensional extended objects: strings. These vibrate (similarly to a violin string) in various modes and can move in space-time. The various particle states that we observe in nature should then all be explained as suitable excitations of suitable strings. Interaction processes between particles are described by splitting and merging of strings. Due to the finite size of strings, many of the divergences that occur for point-like particles can be avoided. The size of the string is very small, typically of the order of a few Planck lengths (1.6×10^{-35} m), so that on large scales string-like particles look like point particles.

Different types of boundary conditions are possible; there are open strings and closed strings. The simplest example is a bosonic string. In suitable coordinates, the equation of motion is simply a wave equation of the form

$$\frac{\partial^2 X^\mu(\sigma, \tau)}{\partial \tau^2} = C^2 \frac{\partial^2 X^\mu(\sigma, \tau)}{\partial \sigma^2}. \quad (1)$$

Here X^μ is the coordinate of the string-like particle in d -dimensional space-time ($\mu = 0, 1, \dots, d-1$), σ and τ denote an internal position and time variable parametrizing the string, and C is a constant.

The general solution can be written as a mode expansion of the form

$$X^\mu(\sigma, \tau) = x^\mu + \dot{x}^\mu \tau + i\sqrt{2\alpha'} \sum_{n \neq 0} \frac{1}{n} \alpha_n^\mu e^{-i\frac{n\pi C\tau}{L}} \cos \frac{n\pi\sigma}{L}. \quad (2)$$

Here x^μ and $\dot{x}^\mu$ are constants independent of σ and τ that essentially represent the position and velocity components of a constantly moving point particle, whereas the sum over n describes the oscillating part of the dynamics. The string parameter $\sqrt{\alpha'}$ describes the approximate scale where string effects become relevant, and L is the length of the string. Unlike a violin string, this string is not tied down at the end points but it can move freely through space-time while it oscillates.

So far this is a classical string. First quantization is done by letting the coefficients α_n^μ of the above normal mode expansion satisfy suitable commutator relations. Second, quantization of strings, up to now, is still an active area of research with many open questions (Kaku, 1999).

The quantization of bosonic strings yields unpleasant surprises, so-called ghosts. These are quantum states with negative norm. One wants to avoid these

Figure 1. A schematic diagram of M-theory with its known string theory limits and the 11-dimensional theory. Some of the dualities are also shown.

unphysical states, which is only possible if the dimension of space-time is $d = 26$. Consequently, it has been necessary to assume that the 22 extra dimensions are “compactified,” that is, curled up on small circles that are so small that we do not notice them in daily life.

But bosonic string theories have another problem. The lowest excitation mode (the ground state) is a so-called “tachyon,” a state for which the mass squared is negative. To avoid this unphysical (unstable) ground state, one proceeds to supersymmetric string theories, in short “superstring theories.” In these theories, for each boson there is a corresponding fermionic partner and vice versa. Technically, one introduces anti-commuting coordinates in addition to commuting ones. For supersymmetric theories, ghost states occur as well, but can now be avoided if the number of space-time dimensions is $d = 10$. So to describe low-energy physics, again six extra dimensions have to be compactified. Five different superstring theories have been found, which are denoted as type I, IIA, IIB, HET $E_8 \times E_8$, and HET $SO(32)$. They differ in the degree of supersymmetry, the underlying gauge symmetry (if any), and whether the strings are closed or open.

Nowadays the five superstring theories are regarded as special limit cases of a more fundamental theory, called M-theory. This contains the five superstring theories and an 11-dimensional theory as special cases. These special cases are marked as the edge points of the diagram in Figure 1. Unfortunately, it is not known how M-theory should be formulated in full generality and how it should be second quantized. It is not even clear what the fundamental objects are that this theory describes. Much work needs to be done.

Some of the string theories contained in M-theory are connected by the so-called duality transformations. S-duality essentially means that a string theory with a small coupling constant α describes the same physics as another string theory with a large coupling given by $1/\alpha$. T-duality means invariance of the physics if

a compactified dimension of radius R is replaced by another one of radius $1/R$.

In recent years, much research emphasis has concentrated on higher-dimensional objects contained in string and M-theory, so-called D-branes. Open strings can end and start on D-branes. Remember that in electromagnetism there are point charges, which are the sources of the electromagnetic field. D-branes are in a sense higher-dimensional generalizations of these point charges.

As already mentioned, to proceed to our four-dimensional world, six of the dimensions of superstring theory (or 7 of those of M-theory) have to be compactified. The way this should be done is unclear. One needs to compactify on special types of compact manifolds, so-called Calabi–Yau manifolds, to preserve what is generally believed to be the right amount of supersymmetry. The compactification step is clearly necessary for string theory to make contact with the real world, but almost all relevant low energy predictions depend on the numerous possibilities of how to compactify. This severely undermines the predictive power of string theories.

In principle, the ultimate theory should predict everything we want to know about particle physics, such as the values of the coupling constants of the four different forces or the masses of all fermions and bosons. In string theories, the numerical values of gauge couplings (e.g. the fine structure constant α_{el} , which is about $\frac{1}{137}$ at low energies) can be related to vacuum expectations of a scalar field contained in string theories, the dilaton field. But this vacuum expectation depends in an unknown way on second quantization effects and has not been predicted so far. As 't Hooft puts it in his book ('t Hooft, 1997), string theory, at least in its present stage, has similarities with a very uncomplete piece of furniture: "Imagine that I give you a chair while explaining that the legs are still missing, and that the seat, back, and armrest will perhaps be delivered soon; whatever I did give you, can I still call it a chair?"

While typical equations for (free) strings, such as Equation (1), are linear, a recent proposal is to amend ordinary strings (evolving in a regular way) by nonlinear versions of strings, so-called chaotic strings (Beck, 2002). These evolve in a deterministic chaotic way. In this approach, each ordinary string is shadowed by a chaotic string, which yields the "noise" for second quantization via the so-called stochastic quantization method. Mathematically, chaotic strings consist of one-dimensionally coupled Tchebyscheff maps, a very nonlinear and strongly self-interacting theory, which describes a kind of "turbulent quantum state" on a small (quantum gravity) scale. It turns out that the vacuum energy of chaotic strings is minimized for observed standard model parameters; that is, in this extended approach to second quantization, concrete predictions

for vacuum expectations of dilaton-like fields and hence on masses and coupling constants can be given.

STRUCTURAL COMPLEXITY

By *structural complexity* we mean the study of morphologically complex patterns associated with many physical entities of dynamical systems, using methods based on algebraic, geometric, and topological information (Ricca, 2001). In this respect, structural complexity offers an alternative and complementary route to study complex systems, based on morphological characteristics rather than the governing rules generating complexity. Structural complexity arises from spontaneous growth and self-organization of interacting components present in the bulk of physical systems, such as in turbulence, in biological and chemical reactions, in growth phenomena, across scales of space, time, and organizational complexity (Badii & Politi, 1997). Much of our understanding comes from observations of natural phenomena, from simulations and computational visualizations. Mathematical methods are used to extract and synthesize the relevant information, and to explore possible relationships between morphological complexity, energy localization, and other physical properties.

Dynamical systems are often characterized by the emergence and interaction of *coherent structures* (Nicolis & Prigogine, 1998; Scott, 2003). These latter are produced through filamentation mechanisms and space-time localization of characteristic physical properties. Examples of coherent filamentary structures may be as disparate as DNA macromolecules, synthetic polymer chains, nerve fibers, actin filaments, vortex filaments, magnetic flux tubes, or massive cosmic

Figure 1. Computational field visualization of a pattern of vortex filaments produced by turbulent flow in a numerical box: (a) low-pressure line and (b) iso-pressure surface, obtained by numerical extraction techniques (Courtesy of S. Kida, Theoretical Division, National Center for Fusion Research, Toki, Japan).

strings. Dislocations and discontinuities in mesoscopic and solid-state physics, fronts and cell membranes in chemistry, fluid dynamics, and biology provide other examples of complex structuring. The formation and continuous re-arrangement of coherent structures are due to local interactions and recombination, governed by specific dynamics given by nonlinear differential equations $\dot{x} = F(x, \lambda)$, with a nonlinear function F of the vector $x = (x_1, \dots, x_n)$, which depends on an external control parameter λ . At certain critical values, this parameter causes phase transitions and pattern changes (Levin, 2002). *Pattern recognition* techniques aim at providing mathematical methods for diagnostics of the morphological complexity of the emerging pattern, regardless of the governing fundamental physical mechanism that is responsible for complexity.

One of the great benefits of modern capability to perform complex three-dimensional simulations is the possibility to effectively analyze and visualize huge sets of three-dimensional data. Direct volume rendering, iso-surface extraction, integral convolution, and many other computational techniques allow sophisticated multi-field visualizations of complex physical patterns (Johnson et al., 2001). Progress in *visiometrics*, based on the exploitation of such techniques for an accurate identification and representation of complex three-dimensional structures, provides powerful tools and an almost inexhaustible source of information for analysis of structural complexity (see Figure 1; also see **Visiometrics**).

Physical as well as computational domains are decomposed into *tropicity* domains, defined by the characterizing properties of nulls, tubes, sheets, and blobs. These are reference sets defined by the reference physical field distribution, that allow direct measurement of the degree of *tubeness*, *sheetness*, and *bulkiness* of the coherent set by analyzing the aspect ratio of the distribution.

Algebraic, geometric, and topological measures are used to quantify structural complexity. In case of high filamentation, the original network of filaments is

Figure 2. Example of analysis of an oriented space curve $\mathcal{L}$, based on crossing number information of the projected curve $\mathcal{L}_p$: we can calculate the total number of un-signed crossings (3, in the example shown in the figure) and, according to the sign convention shown on the right-hand side of the diagram, the algebraic sum of the $\pm$ signs ($-1 - 1 + 1 = -1$, in the example shown). By averaging these two quantities over all directions p of projections, we obtain estimates of, respectively, the average crossing number and the writhing number of $\mathcal{L}$.

reduced (by appropriate threshold filtering) to a tangle $\mathcal{T}$ of space curves (representing the filament axes), hence reducing the problem to the analysis of the mutual positioning of the system of curves in space. By using methods based on crossing number information, we can evaluate the *average crossing number* $\bar{C}$ of the tangle that provides a fundamental algebraic measure of structural complexity. This quantity is defined by the formula

$$\bar{C} = \sum_{\mathcal{L}_i, \mathcal{L}_j \in \mathcal{T}} \bar{C}_{ij}, \quad (1)$$

where

$$\bar{C}_{ij} = \left\langle \sum_{r \in \mathcal{L}_i \cap \mathcal{L}_j} |\varepsilon_r| \right\rangle, \quad \varepsilon_r = \pm 1 \quad (2)$$

denotes the un-signed crossings between the curve $\mathcal{L}_i$ and $\mathcal{L}_j$ of the tangle $\mathcal{T}$, and summation is made over all the crossings resulting from $\mathcal{L}_i \cap \mathcal{L}_j$; the average number of crossings is then evaluated by projecting the tangle onto projection planes; here the angular brackets denote averaging over all directions of projections (in the simple case of one oriented space curve, Figure 2 shows an application of this analysis). Geometric measures are based on integral measures of curvature and torsion of the reference curves and surfaces; for tangles of curves, these include *total curvature*, *average twist*, and *writhing number* which give information on the amount of coiling and entwinement of the corresponding filaments. Topological information comes from different types of measures: number of *nulls* (zero-value field singularities), *linking numbers* for open or closed curves, winding numbers and invariants associated with handle-body decomposition of reference sets are all calculable quantities. Further information may come from analysis of cell-decomposition of the network. In particular situations, when a prevailing type of

geometry emerges, ad hoc analysis is used; for example, spiral spectrum analysis can be employed for scroll-wave reactions in Belousov–Zhabotinsky-type chemical systems and braid theory can be applied to study dynamics of particulates, fluid mixing, trailing vortices, astrophysical plasma loops, and tangle diagrams for polymers. Other information may come from study of dynamical systems, where we have information, for example, on Lyapunov exponents, topological entropy, multifractal properties, and topological scaling (see, for example, de Gennes, 1979; Jensen, 1998), whereas artificial intelligence provides us tools based on algorithmic complexity for neural-type networks. Measures of structural complexity are implemented computationally as time-dependent variables that change with the evolution of the physical system.

Collected information on structural complexity is analyzed against physical information. Since the evolution of any physical system is driven by variational principles that take account of energy and entropy redistributions, information on structural complexity may disclose some useful information on the physics and dynamics of the process. It is known that geometric properties strongly influence the dynamics: curvature forces (such as bending force in elastic rods or surface tension in liquid films) cause telephone cords to coil-up and foam bubbles to coalesce. We, therefore, expect relationships between geometry, dynamics, and ultimately, energy. Possible relationships between energy, entropy, and structural complexity in terms of algebraic information have, however, a more subtle rationale: network restructuring is due to local interactions and recombinations that are induced by acting potentials. These are associated with localized coherent structures, acting either on the strands of neighboring filaments (as in the case of reconnection of vortex tubes) or on the surface elements of sheet discontinuities (as in the formation of elastic films). In this context, local interaction of neighboring structures, resulting in the emergence of apparent crossings (possibly weighted by some distribution function) is a measure of the localization of internal energy. Hence, the resulting growth rate of the average crossing number provides an estimate of energy and entropy variations in the system. In absence of dissipation, topology is conserved; however, even in fully dissipative systems, topological information provides indications to detect preferred paths of energy depletion. In general, if χ denotes a measure (or a family of measures) of structural complexity, and E the energy of the system, we may expect *energy-complexity relations* of type $E = G(\chi)$, where G is a nonlinear function, where the nonlinearity is prescribed by the growth rate exponents of the physical process (see, e.g., Barenghi et al., 2001). Algebraic, geometric, and topological measures of structural complexity are, therefore, not only useful for computational implementation of diagnostics and

pattern recognition, but they can also provide new tools to investigate localization and transfer of energy in complex physical systems.

SUBHARMONIC GENERATION

See **Harmonic generation**

SUPERCONDUCTING QUANTUM INTERFERENCE DEVICE

The Superconducting Quantum Interference Device (SQUID) is the most sensitive detector for magnetic flux, Φ . It relies on the fundamental concept of flux quantization in a multiply connected superconductor, for example, a ring (torus). Flux quantization is a clear demonstration of the quantum mechanical properties of a superconductor in which the conduction electrons form (Cooper) pairs and condense in the ground state: the so-called “Bose condensation.” Below the transition temperature, T_c , all the bosonic pairs can be described by a single macroscopic many-body wave function

$$\Psi(\mathbf{r}) = [n_s(\mathbf{r})]^{1/2} e^{i\theta(\mathbf{r})}, \quad (1)$$

where n_s is the density of Cooper pairs. The phase $\theta(\mathbf{r})$ is a scalar function of the position. For small fields one may ignore the spatial dependence of n_s .

A direct consequence of the condensation is that for $T < T_c$ a superconductor exhibits zero electrical resistance and that magnetic fields are expelled from its interior. However, this diamagnetism (Meissner effect)

Figure 1. (a) The RF-SQUID and (b) the DC-SQUID. Dashed line is an integration contour deep inside the superconductor.

is not perfect as currents may penetrate into a thin surface layer (about 50 nm) called the London penetration depth (λ_L).

Early superconductors were metals (Hg, Al, Sn, Pb, Nb) or alloys (NbTi, Nb₃Sn) with T_c below ≈ 20 K. Since 1986, a new class of ceramic materials has been discovered with transition temperatures in the range 50–135 K, meaning that instead of requiring cooling by liquid helium (4 K), they only need cooling with liquid nitrogen (77 K) or by traditional cryocoolers. The terms low- T_c (LTS) and high- T_c (HTS) are used for these two types of superconducting materials.

The gradient of the phase θ of the macroscopic wave function describing all Cooper pairs depends on the pair-current density, $\mathbf{J}_s$, and the magnetic vector potential, $\mathbf{A}$, as

$$\hbar \nabla \theta = 2e(\Lambda \vec{J}_s + \vec{A}), \quad (2)$$

where the pre-factor, $\Lambda = 2m/n_s(2e)^2$, reflects the double electron charge $2e$ and mass $2m$ of the Cooper pair. If Equation (2) is integrated along a closed contour deep inside the superconducting ring where $\mathbf{J}_s = 0$, the fact that the wave function has to be single-valued with phase (modulo 2π) leads to quantization of the magnetic flux contained in the ring so that

$$\Phi_{\text{encl}} = n\Phi_0, \quad (3)$$

where $n = 0, 1, 2, 3, \dots$ is an integer and $\Phi_0 = h/(2e) = 2.07 \times 10^{-15}$ Wb is the “flux quantum.” Φ_0 is very small, corresponding to the flux generated by the Earth’s magnetic field ($\approx 40 \mu\text{T}$) in a circular loop with radius $\approx 4 \mu\text{m}$.

A SQUID is a superconducting ring including either one or two Josephson junctions as shown in Figure 1. Named after their operational modes, these are called the RF-SQUID and the DC-SQUID. In both configurations, the response to an external magnetic flux is periodic in the flux quantum Φ_0 . For simplicity, we consider only the two-junction DC-SQUID shown in Figure 1b.

Upon integrating Equation (2) along the closed contour, one may show that the difference between the phases, φ_1 and φ_2 , of the macroscopic wave functions of the two Josephson junctions varies periodically with

Figure 2. Magnetic interference pattern of symmetric DC-SQUID. Total critical current versus applied magnetic flux, $\beta_L = 0$.

the applied flux Φ as

$$\varphi_1 - \varphi_2 = 2\pi \Phi / \Phi_0, \quad (4)$$

giving a total critical (super-)current, I_{Tc} , of the SQUID

$$I_{Tc}(\Phi) = I_{c1} \sin \varphi_1 + I_{c2} \sin(\varphi_1 - 2\pi \Phi / \Phi_0). \quad (5)$$

For two identical ($I_c = I_{c1} = I_{c2}$) junctions, $I_{Tc}(\Phi)$ varies from $2I_c$ to zero with a period of Φ_0 (see Figure 2). The first zero is at $\Phi = \Phi_0/2$. We say that the depth of modulation, $M = I_{Tc,\text{max}}/I_{Tc,\text{min}} = I_{Tc}/2I_c$, is 100%. M is reduced if the two junctions are different.

The variation in $I_{Tc}(\Phi)$ reflects the fact that the applied flux generates a circulating shielding supercurrent, $I_{\text{circ}}(\Phi)$ in the SQUID ring. Given the loop inductance, L , it generates a self-flux $\Phi_{\text{self}} = LI_{\text{circ}}$, which counteracts the applied flux. The effective flux in the ring is only $\Phi = \Phi_{\text{appl}} - \Phi_{\text{self}}$ leading to a reduced depth of modulation. A practical measure for a symmetric SQUID is the inductance parameter $\beta_L = \pi L I_c / \Phi_0$. For $\beta_L = 0$, $M = 100\%$ (as above) while for $\beta_L \rightarrow \infty$, $M \rightarrow 0$. Practical DC-SQUIDs are optimized with $M \approx 50\%$ corresponding to $\beta_L \approx 1$.

In order to avoid complications caused by hysteresis and flux contained in finite size junctions, one usually keeps junctions small and nonhysteretic (i.e., with relatively large damping and small capacitance). DC-SQUIDs with such junctions can be stably biased in the voltage state using a fixed DC current $I_b > I_{Tc}$. When an external flux is applied, the I-V curve is shifted following $I_{Tc}(\Phi)$, given in Equation (5), and a sensitive measurement of the oscillating voltage, $V(\Phi)|_{I_b}$, across the SQUID enables determination of Φ to a small fraction of Φ_0 . Generally, the flux resolution is limited by thermal noise.

The use of a SQUID as a detector is complicated by the highly nonlinear dependence of the voltage response on the applied flux (see Figure 2). This may be overcome by operating the SQUID in the so-called

“flux locked mode,” where the SQUID output voltage via a feedback loop is returned as a current in a coil placed near the SQUID ring. By proper design, the coil produces a flux that exactly compensates the applied flux in the ring. The SQUID now acts as a null detector where the feedback current is a linear function of Φ over a very large range of magnetic flux.

Its impressive flux resolution does not imply that the SQUID can resolve such small magnetic fields, because the area of the SQUID ring is normally very small. An ingenious way to effectively increase the loop area without increasing L (keeping $\beta_L \leq 1$) is to use a superconducting flux transformer. This is a closed superconducting loop consisting of a series connection of a pickup coil placed in the ambient magnetic field and an *input coil* inductively coupled to the SQUID ring. When an external magnetic field is applied to the pickup coils, a shielding current is set up in the loop so that the total flux in the flux transformer is conserved (flux quantization). The current generates a flux in the input coil, which in turn couples the flux into the SQUID. To increase sensitivity, the input coil often is a multilayer thin-film coil (Washer type) placed on top of the SQUID ring. Usually, the input coil and the SQUID are enclosed in a magnetic shield to suppress external noise.

A well-designed LTS DC-SQUID magnetometer with proper pickup coil has an unsurpassed magnetic field sensitivity of ≈ 10 fT (10^{-14} T), about one billionth (10^{-9}) of the Earth's magnetic field. LTS RF-SQUIDS and HTS DC-SQUIDS reach 100 fT. Most field measurements, therefore, are limited by magnetic noise from the environment and not from the magnetometer itself. Magnetic noise may be dramatically reduced by shaping the pickup coil as two matched counterwound coils, so that a uniform magnetic field (e.g., from a distant source) generates zero net flux in the flux transformer. Effectively it measures the gradient of the magnetic field working as a first-order gradiometer with baseline equal to the distance between two counterwound coils. Higher order gradiometers with three (or more) balanced coils have also been constructed. Modern multi-SQUID magnetometers use first-order gradiometers with advanced digital noise reduction and background field nulling.

Because of their high sensitivity, SQUIDS are now used as transducers for virtually any response that can be converted to magnetic flux, including magnetic fields, field gradients, currents, voltages, electromechanical positioning, and movements. A prominent biomedical application is three-dimensional magnetic source imaging, where an array of several hundred SQUIDS placed in a helmet fitted around the head can localize magnetic sources in the human brain to about a millimeter. This is important for precise location before or during brain surgery and for diagnosis of mental disorders. Many hospitals already use commercial SQUID instruments to record

the very weak fields generated by nerve pulses in the brain (MEG, magnetoencephalogram) and heart, even the fetal heart beat (MCG, magnetocardiogram), as supplements or improved alternatives to the established electrical counterparts, EEG (electroencephalogram) and ECG (electrocardiogram) using electrodes placed on the skin.

Dedicated SQUID magnetometers are also used in geomagnetic surveying as well as for nondestructive testing (NDT), where defects in conducting samples can be detected by monitoring magnetic fields of induced eddy currents. For detection of the Earth's magnetic field, signal frequencies are typically a few millihertz, but SQUIDS may also be used for ultra-low noise microwave amplifiers as well as picosecond electronics and terahertz oscillators based on propagation at high speed of single quanta of magnetic flux in SQUID arrays.

SUPERCONDUCTIVITY

The phenomenon of superconductivity was discovered in 1911 by the Dutch scientist Heike Kamerlingh Onnes. In connection with work on the liquefaction of helium (normal boiling point at 4.2 K), he measured the resistance of mercury and noticed that the resistance dropped gradually with temperature as was expected. However, near 4.2 K, the resistance apparently dropped to a very small value consistent with zero. This, of course, must have been a very dramatic discovery, changing completely the general picture of the properties of solid-state matter. Today, the simple and direct consequence of zero resistance—that a large current can run indefinitely in a closed wire without energy input—intrigues many people. Even though zero resistance may be counter-intuitive, it is not forbidden by the laws of nature, and it does not imply a “perpetuum mobile.” The second important property of a superconductor is that it is a perfect diamagnet. This property also has a feature that at first may seem quite unnatural. If a magnet is lowered towards a superconductor, the magnetic field of the magnet cannot penetrate into the superconductor. The magnetic field lines become compressed between the magnet and the superconductor, and eventually the magnet will levitate. This exclusion of the magnetic field is not a consequence of the

Figure 1. A levitated HTS superconductor.

induction law in connection with zero resistance of the superconductor, but an independent phenomenon. The phenomenon was discovered in 1933 by Walter Meissner and Robert Ochsenfeld long after the discovery of zero resistance. It is called the Meissner effect.

Superconductivity as discussed above occurs in many ordinary metallic elements from the periodic table. Examples are mercury, lead, tin, and niobium. The transition temperatures T_c (i.e., the highest temperature where superconductivity occurs) are typically below 10 K. If the external magnetic field is too high, it will quench the superconductivity completely. This field is called the critical field H_c , and it is typically of order some hundreds of Gauss, too low for practical applications in electric machinery. The type of superconductor described above is called a type I superconductor.

Type II superconductors were discovered much later—in the 1950s. They are typically alloys of metals such as NbTi or Nb₃Sn and have transition temperatures typically in the 10–20 K range up to 23 K. They can carry much higher currents and can withstand much higher magnetic fields, thus, being much more useful for applications. A major difference from type I superconductors is the way they behave in a magnetic field. The Meissner effect as described above exists up to a so-called lower critical field H_{c1} . At H_{c1} , the magnetic field in the form of magnetic flux lines starts to penetrate the superconductor. As the external field is increased up to the upper critical field H_{c2} , more and more flux lines penetrate the superconductor until at H_{c2} , the flux lines completely fill the superconductor, which then becomes normally conducting.

In 1986, a new type of superconductor was found with a complicated structure. These superconductors are called High Temperature Superconductors (HTS, see below) and may, for lack of better understanding, be described as extreme type II. Examples are YBa₂Cu₃O₇ (known as YBCO) and Bi₂Sr₂Ca₁Cu₂O₈ (BSCCO), both of which have transition temperatures above the boiling point of liquid nitrogen at 77 K. These materials are quite useful for applications since liquid nitrogen—a cheap industrial product—may be used as a coolant. These important superconductors will be discussed separately below.

Figure 1 shows a levitated HTS superconductor. Since it is an extreme type II superconductor, magnetic

flux lines penetrate the superconductor. These flux lines are “pinned” on imperfections of the crystal lattice, such as dislocations, and provide a stability not seen in type I superconductors. Thus, the HTS superconductors may even “levitate” below the magnet—hanging on the flux lines from the magnet. By symmetry a magnet can also be levitated over a superconductor.

Ginzburg–Landau Theory

Superconductivity is a complicated quantum mechanical phenomenon. The particles giving rise to the supercurrents may be described by a quantum mechanical wave function $\psi(r) = |\psi(r)|\exp(i\Theta)$. In a normal metal, the phases of all the electrons are different. In the superconducting state, all carriers have the same quantum mechanical phase of the wave function. This is referred to as macroscopic phase coherence. Thus, a simply connected macroscopic superconductor is characterized by a single-phase angle. The difference between a normal metal and a superconductor has some similarity to the difference between the coherent light of a laser, where all the atomic oscillators oscillate in phase and the “white” light of an ordinary bulb, where all the excited atoms are incoherent.

The interpretation of superconductivity as a macroscopic quantum phenomena and the first useful theory of superconductivity were due to Fritz and Heinz London in 1935.

A real breakthrough for applications is the still very often-used phenomenological theory published by the Russian scientists Vitaly Ginzburg and Lev Landau in 1950. Ginzburg and Landau introduced a position-dependent order parameter with a conceptual similarity to a quantum mechanical wave function. The Ginzburg–Landau theory is a masterpiece of intuition. It postulates that as the temperature is lowered and T_c is crossed from above, a (complex) order parameter $\psi(r)$ for an ordered, superconducting phase appears—increasing from the value zero at T_c . Gibbs free energy is then expressed as a series expansion in terms of this order parameter $\psi(r)$. Finding the equilibrium value of the Gibbs free energy leads to two coupled differential equations that connect the order parameter and the electromagnetic fields.

Variational methods are used and the Ginzburg–Landau equation is derived. It may be written

$$\alpha\psi(r) + \beta|\psi(r)|^2\psi(r) + 1/2m((\hbar/2\pi i)\nabla - q\mathbf{A})^2\psi(r) = 0$$

Here α and β are coefficients to be determined by the particular system, $\mathbf{A}$ is the vector potential and m is a particle mass. The last term on the left side has the appearance of a kinetic energy, and we note the similarity to the Schrödinger equation (See **Nonlinear Schrödinger equations**).

As mentioned above, the nonlinear Ginzburg–Landau equation can be applied to other systems with an order parameter characterizing a phase transition. Examples are magnetic materials, liquid helium, and liquid crystals. Because of the series expansion, which is only good when the expansion parameter is small, the theory is formally only valid near the transition temperature.

BCS Theory

Although rather successful, the above theories are phenomenological in nature. They do not specify the nature of the physical system or why superconductivity occurs. For this, a full microscopic quantum mechanical theory must be derived. This was done by John Bardeen, Leon Cooper, and Robert Schrieffer in 1957, and their theory carries the name BCS theory. The derivation of the BCS theory is too complicated to be described here, but we note that in most practical cases a full understanding is not needed. Close to T_c the BCS theory approaches the phenomenological Ginzburg–Landau theory as it should. Central to BCS theory is the notion that there are two types of currents. Normal currents are carried by normal electrons, and supercurrents are carried by so-called “superelectrons.” Just below T_c , there are only a few superelectrons and many normal electrons. At $T = 0$, all charge carriers are superelectrons. These “superelectrons” are bound pairs of normal electrons called Cooper pairs. Accordingly they have two electron masses and two electron charges. Intuitively, one would think that two electrons could not form a pair since Coulomb repulsion would rip them apart. However, the pairing mechanism has its origin in the electron-phonon interaction, which is responsible for overwhelming the Coulomb repulsion and providing the attractive potential binding the two electrons together.

The binding energy of the pair, Δ , is of order a few meV and is related to the energy scale of the phonons involved in the pairing process. Naturally in the BCS theory, there is a direct proportionality between the transition temperature T_c and the pair binding energy Δ . In fact, this way it has been suggested that T_c s cannot exceed about 30 K. Until recently the highest T_c observed experimentally was 23 K in general agreement. This is not true any more as will be described in the next section.

High T_c Superconductors

In 1986, K. Alex Muller and J. Georg Bednorz from the IBM Zurich research laboratory discovered superconductivity in a new class of materials involving typically the so-called rare earths. Within a few months after the discovery was known, researchers found a T_c of 92 K in the material $\text{YBa}_2\text{Cu}_3\text{O}_7$ and related

compounds. YBCO is typical of the so-called HTS although now many other families are known, including the widely used $\text{Bi}_2\text{Sr}_2\text{Ca}_2\text{Cu}_3\text{O}_8$ compounds. To become superconducting, these materials must undergo a heat treatment at about 1000 K in an oxygen atmosphere. After this baking, the materials appear as a ceramic and are thus hard and brittle—which causes some engineering problems for making the superconductors into wires and coils. Now, many more HTSs are known and the highest T_c found so far is about 150 K. New HTS materials are found regularly, and it cannot be predicted what the limit to higher T_c will be. Maybe we will one day have room-temperature superconductors.

The theory for HTSs is not known, in spite of the efforts of many theoreticians. Obviously, the BCS theory is not directly applicable since it predicts a maximum T_c of about 30 K. An HTS typically has a layered structure with copper-oxide planes separated by isolating atoms at atomic distances, and it is speculated that the superconductivity somehow has its explanation in this structure.

Particularly following the discovery of HTS, the potential for useful applications of superconductivity is quite large. A significant benefit of the high transition temperatures is that liquid nitrogen at 77 K can be used as the coolant. Applications are both small scale (electronics, sensors, and communications) and large scale (power cables, motors, transformers, and large magnets.)

Starting with small scale, we note that Josephson junctions (See **Josephson junctions**) are the main component in superconducting electronics. The general advantage over semiconductors is higher speed and lower dissipation. Computers can be constructed that are much faster and much smaller than conventional computers. Sensors, in general, can be made much more sensitive with superconductor technology. This is because of the quantum mechanical nature of superconductivity and, of course, the low temperatures where thermal noise is reduced. A so-called superconducting quantum interference device (SQUID) is a commercial superconducting magnetic field sensor that is so sensitive that it can measure the magnetic field from nerve impulses in the brain. It can also be used to detect internal cracks in the aluminum-alloy plates of aircraft wings. Superconducting photon detectors can detect single photons from space. High-frequency microwave detectors can detect signals down to the quantum limit and in some spectacular cases even lower. Filters for mobile telephone ground stations can be made much sharper than conventional ones, implying more telephones, improved quality, and lower prices.

Large-scale applications include large magnets, levitated trains, power cables, motors, energy storage, and fault current limiters. Large magnets are, for example, used in the Magnetic Resonance Imaging

(MRI) systems at hospitals where a patient's whole body is introduced into the magnet. This is a very large market, and it is only feasible with superconducting magnets. A levitated train with superconducting magnets has already been built in Japan (Maglev). Superconducting (HTS) power cables have already been built in several countries. In Denmark, a 35 m section has already been installed in the Copenhagen grid. In general, the benefits of the superconducting systems is that energy savings can be obtained because there is no—or at least very low—dissipation. Thus superconducting machinery can be made much smaller than similar conventional machinery, which is important in many cases in the automotive industry. Energy can be stored in large superconducting coils or friction-free flywheels. A fault current limiter is an important protection device for the utility grid that can be made using only superconducting technology.

In the coming generation, superconductivity may play the revolutionary role that semiconductors did in the previous generation.

SUPERFLUIDITY

Superfluidity is the state of a quantum liquid in which the liquid has the ability to flow through fine slits and capillaries without friction or production of a pressure gradient. The superfluidity of liquid helium He^4 (called “He-II”) at temperatures below $T_\lambda = 2.17\text{ K}$ was discovered by Peter Kapitza in 1938. The transformation of normal liquid helium into the superfluid state is a phase transition of the second order. Nevertheless, the superfluid He-II cannot be considered as a liquid without viscosity. Experiments on rotational vibrations of a disk suspended in He-II show that damping is observed at temperatures below ($T < T_\lambda$), decreasing as the temperature is lowered.

The first qualitative explanation of superfluidity phenomena was proposed by Lazlo Tisza (1938), who introduced a two-fluid model of superfluidity. Lev Landau (1941) later formulated a so-called two-fluid

Figure 1. Dependence of the energy of elementary excitations on momentum.

hydrodynamics of He-II. According to this explanation, He-II consists of two interpenetrating fluids, a normal fluid with viscosity and a superfluid fluid with zero viscosity. It is the superfluid that flows without friction through the finest of channels, while the finite viscosity of the normal component is responsible for the observed damping of the oscillating disk. Each component is assigned a density ρ_n and ρ_s , whose sum is the total density $\rho = \rho_n + \rho_s$, and each is assigned its velocity field v_n and v_s .

Landau's theory is based on the idea of a possible description of physical properties of a weakly excited macroscopic system at low temperatures by means of elementary excitations or “quasiparticles.” The elementary excitations have energy $\varepsilon(p)$ and are regarded as particles of momentum p . The normal component represents a gas of elementary quasiparticles with a dispersion curve as sketched in Figure 1. There are two types of the quasiparticles at low temperatures: sound quanta or phonons of long wavelength (with dispersion relation $\varepsilon = sp$, where s is the sound velocity) and excitations of short wavelength called “rotons” (near the minimum of the curve in Figure 1 their energy is $\varepsilon = \Delta + \frac{1}{2}(p - p_0)^2/\mu$), where μ is the effective mass of the roton). Interactions of quasiparticles with each other and with the vessel's walls cause the viscosity of the normal component. At zero temperature, the normal density $\rho_n = 0$ and the system is in the ground state.

The remaining part of He-II is the superfluid component. It has zero viscosity and can move without friction through narrow slits and capillaries if the energy spectrum of the quasiparticles satisfies the following condition: $\varepsilon(p)/p > 0$. At $T = 0$, the superfluid density $\rho_s = \rho$. The quasiparticle concentration grows when the temperature increases and ρ_s decreases turning into zero at $T = T_\lambda$. According to the Landau theory, the liquid loses the superfluidity property if the velocity of its flux exceeds a critical velocity,

$$v_c = \min(\varepsilon(p)/p); \quad (1)$$

this condition is called the “Landau criterion.” Real critical velocities are much less than (1) because

the superfluidity is broken by vortices arising in the superfluid liquid at even smaller velocities. Quantum vortices have been observed during experiments on the motion of the He-II in a rotating cylindrical container.

In a quantum Bose gas and He-II at low temperatures, a large number of particles (a finite proportion of all particles) turns into one coherent state called a "condensate," which can have a stationary velocity different from zero. Such a phenomenon is called "Bose–Einstein condensation," and superfluidity is often connected with it. When the superfluidity component is a correlated many-particle quantum state; however, it may not be connected directly with Bose–Einstein condensation.

The energy spectrum of excitations in a weakly non-ideal Bose gas with repulsive interactions between particles was first derived by Nikolai Bogolubov (1947) assuming existence of the condensate

$$\varepsilon(p) = [(p^2/m)\rho_0 v(p) + p^4/(4m^2)]^{1/2}, \quad (2)$$

where ρ_0 is the density of particles in the state $p=0$, $v(p)$ is the Fourier component of the potential of interparticle interaction ($v(0) > 0$), and m is the mass of the particle. Equation (2) determines a spectrum of small vibrations of the condensate in the non-ideal Bose gas. This dispersion relation is of the phonon type at small p , where the Landau criterion is satisfied. Therefore, even the weakly non-ideal Bose gas possesses the superfluid property.

A macroscopic theory of the superfluid dynamics of the weakly non-ideal Bose gas was developed by Gross (1961) and Pitaevskii (1961). In this theory, a condensate wave function Ψ is described by the nonlinear Schrödinger equation ($\hbar = 1$):

$$i \frac{\partial \Psi}{\partial t} = -\frac{1}{2m} \Delta \Psi + v(0) (|\Psi|^2 - \rho) \Psi. \quad (3)$$

A solution of the linearized Equation (3) has a form of harmonic vibrations whose frequency spectrum is determined by Equation (2). Thus, Equation (3) in a total form possesses a solution in the form of the straight-line vortex

$$\Psi = \sqrt{n} f\left(\frac{r}{r_0}\right) e^{i\phi}, \quad r_0^2 = \frac{\hbar^2}{2m v(0) n}, \quad (4)$$

where r and ϕ are the distance from the vortex axis and the polar angle with respect to it, and the function $f(r)$ has a shape sketched in Figure 2.

Superfluidity is also possible in quantum Fermi liquids both in neutral (e.g., liquid He³) and charged (conducting electrons in metals) liquids. Then a generation of pairs of coupled fermions is necessary (pairs of He³ atoms or electrons with an integer spin) to create bosons. Such pairing is a result of any attraction (either van der Waals interactions between the atoms or interaction of the electrons with vibrations of the crystal lattice). Being bosons, these "Cooper

Figure 2. Distribution of the condensate near the vortex.

pairs" can form coherent superfluid condensates. The attractive forces between He³ atoms are very small; therefore, conditions for generation of the Cooper pairs of quasiparticles and origin of the superfluidity of He³ appear only at superlow temperatures of the order of 10⁻⁶K. Interestingly, there are two superfluid phases (A and B) of the He³ at superlow temperatures.

The emergence of electron Cooper pairs in a metal corresponds to the appearance of superconductivity. Concepts from superfluidity theory have influenced the theory of superconductivity in metals and also the development of models of the superfluidity of the atomic nucleus. As the atomic nucleus presents a Fermi system with strong interparticle interaction, both the pair correlation effects and also manifestations of some superfluid properties of Bose systems should take place.

Superfluid liquids possess several unusual properties. Besides ordinary sound (i.e., vibrations of the liquid's density), a so-called "second sound" can propagate in such a liquid. The second sound represents sound propagation in the quasiparticle gas (vibrations of the quasiparticle density and, therefore, vibrations of the temperature). Also, a thin film of superfluid He-II forms on a solid wall, rising easily up to a large height. This film can equalize liquid levels of the helium in vessels having a common wall.

SUPERLATTICES

Superlattices (SLs) are solid periodic structures usually made artificially and having a period much larger than the interatomic distance. The SL is called one-dimensional (1-d) if it is periodic along one axis. In such a case, the SL has the form of alternating plane-parallel layers of two or several materials differing in their physical properties (dielectric, elastic, magnetic, etc., depending on the implementation of interest) (see Figure 1). Modern techniques of crystal growth allow the creation of artificial crystals with atomic smooth boundaries between layers, which can be arranged in any order. A two-dimensional SL is periodic in two directions and homogeneous in the third, and a three-dimensional SL is periodic along three axes. There are many types of SLs, including semiconducting and superconducting SLs, dielectric or optical SLs (called photonic crystals), and elastic or acoustic SLs (called phononic crystals).

The main physical property of an SL important for applications is a band structure of the energy or frequency spectrum caused by the macroscopic periodicity analogous to the structure of electron energy or phonon frequency spectra in monocrystals.

The physical origin of the band structure can be understood by analyzing a one-dimensional SL constructed from two types of materials, where the alternating layers have thicknesses d_1 and d_2 (see Figure 1). The SL period equals $d = d_1 + d_2$, and the electromagnetic or elastic fields inside each layer are described by wave equations with phase velocities c_1 and c_2 . Thus, eigenfunctions of the wave equations are characterized by a quasiwave number k , and the energy or frequency of any excitation is a periodic function of k with the period $2\pi/d$, so values of k can be restricted to the one-dimensional Brillouin zone $-\pi/d < k < \pi/d$.

If the velocities c_1 and c_2 are close, one can assume $c_1 = c_2 = c$ in the first approximation, so the dispersion relation for the wave solution is that for

Figure 1. 1D SL made of substances of two types A and B.

Figure 2. Dispersion relations for the SL (a) in the limiting case $c_1 = c_2$ and (b) in the case $|c_1 - c_2| \ll c_1 \approx c_2$.

a homogeneous material. In the case of an elastic medium or a dielectric transparent for electromagnetic waves, $\omega(k) = ck$ where ω is the frequency and c is either the sound or light velocity (the straight lines in Figure 2a). Because the function $\omega(k)$ repeats itself outside the Brillouin zone, the lines fold back into the zone when they reach edges. A small perturbation provided by the small difference between c_1 and c_2 takes off the degenerations at the points $k = 0, \pm \pi/d$ and as a result, a small frequency gap appears between the upper and lower branches of the lines (Figure 2b). This is called a forbidden gap as no excitation mode of the SL can exist in the gap. As the difference $c_1 - c_2$ is increased, the forbidden gap widens considerably.

Dispersion equations for the frequencies of arbitrary one-dimensional SLs made of two dielectric or elastic materials were obtained by the Soviet scientist Sergei Rytov (1955, 1956) using the standard boundary conditions at the layer boundaries

$$\cos kd = \cos k_1 d_1 \cos k_2 d_2 - \frac{1}{2} \left(\frac{k_1}{k_2} + \frac{k_2}{k_1} \right) \sin k_1 d_1 \sin k_2 d_2, \quad (1)$$

where $k_1 = \omega / c_1$ and $k_2 = \omega / c_2$. When the right-hand side of Equation (1) has values from -1 to $+1$, the equation has real roots, which give the values of ω .

If one of the alternating layers is opaque for electromagnetic waves, the corresponding wave vector is imaginary: $k_2 = i\kappa_2$ and Equation (1) transforms to

$$\cos kd = \cos k_1 d_1 \cosh \kappa_2 d_2 - \frac{1}{2} \left(\frac{k_1}{\kappa_2} - \frac{\kappa_2}{k_1} \right) \sin k_1 d_1 \sinh \kappa_2 d_2. \quad (2)$$

There are two limiting cases of Equations (1) and (2) when the roots of interest can be easily obtained either graphically or analytically. The first one concerns (2) and assumes $\kappa_2 = \text{constant} \rightarrow \infty$ and $d_2 \rightarrow 0$ at $\kappa_2 d_2 \rightarrow 0$ under the condition $\kappa_2^2 d_2^2 = \text{constant} = q$ (Kronig & Penny, 1931). The simplified version of Equation (2) has the form

$$\cos kd = \cos k_1 d + M \frac{\sin k_1 d}{k_1 d}, \quad M = \frac{1}{2} q d, \quad (3)$$

which can be solved graphically. In Figure 3a, $z = k_1 d$ and the roots of the equation run over values within intervals marked off on the abscissa axis. These intervals become wider and the forbidden gaps become more narrow when the frequency increases.

The second limiting case concerns Equation (1) and corresponds to the limit $d_2 \rightarrow 0$, $c_2 \rightarrow 0$ under the conditions $d_2/c_2 = 0$ and $d_2/c_2^2 = P = \text{constant}$, leading to (Kosevich, 2001)

$$\cos kd = \cos k_1 d - Q k_1 d \sin k_1 d, \\ Q = c_1^2 P / (2d). \quad (4)$$

Equation (4) can also be solved graphically (see Figure 3b), and a set of permitted intervals contracting with increasing frequency can be obtained. However, there is an analytical expression for frequencies at large numbers m of these intervals ($m^2 Q \gg 1$)

$$\omega = \frac{m\pi c}{d} + \frac{2\Omega}{m} \begin{cases} \sin^2(kd/2), & m = 2p; \\ \cos^2(kd/2), & m = 2p + 1, \end{cases} \quad (5)$$

where $\Omega = c/(\pi Qd)$ and p is an integer.

The frequencies of forbidden bands correspond to a solution of the wave equation inside n -th layer of the type $\exp \pm \kappa nd$ (when $k = i\kappa$) or $(-1)^n \exp(\pm \kappa nd)$

Figure 3. Graphical solutions of (a) Equation (3) and (b) Equation (4). Eigenfrequency bands are shown in heavy lines on the z -axis ($z = k_1 d$).

(when $k = i\kappa + \pi$), which decrease (grow) with increasing n . The frequency dependence of the parameter κ for solutions of the first (second) type is found from Equation (1) when its right-hand side is larger than $+1$ (then $\cos kd = \cosh \kappa d$ in the left-hand side) or less than -1 (then $\cos kd = -\cosh \kappa d$). Such solutions have a physical meaning only in the x semiaxis under the condition that a solution vanishing at infinity and corresponding to certain boundary conditions at the origin is selected. The necessity of using exponentially decreasing solutions arises in describing localized states of fields under consideration in the vicinity of a local SL defect. Of course, a one-dimensional SL can have only localized states near a given plane. In certain circumstances, a localized mode can exist at the face of the SL (called a surface state).

In the general case, the spectrum of an SL is complicated and contains a system of a great number of both eigenfrequency bands and gaps corresponding to forbidden frequencies of eigenmodes. No extended states are allowed in the gap, but there exist evanescent modes, decaying exponentially with increasing the distance from the defect. In a three-dimensional SL, they are localized states.

Dependence of the physical parameters of materials (the velocities c_1 and c_2 , or the parameters Q and M in the above equations) on the field strength leads to nonlinear effects in SLs. In optical SLs, a source of nonlinear effects is the dependence of the refraction coefficient on the electric field of a light wave. In the simplest case, which corresponds to the

dispersion relations (5) in the linear approximation, an electromagnetic wave Ψ_n in the n th layer of the SL is governed by the discrete NLS equations for $m = 2p$

$$i \frac{\partial \Psi_n}{\partial t} = \frac{m\pi c}{d} \Psi_n - U_0 |\Psi_n|^2 \Psi_n - \frac{2\Omega}{m} (2\Psi_n - \Psi_{n+1} - \Psi_{n-1}) \quad (6)$$

and for $m = 2p + 1$

$$i \frac{\partial \Psi_n}{\partial t} = \frac{m\pi c}{d} \Psi_n - U_0 |\Psi_n|^2 \Psi_n + \frac{2\Omega}{m} (2\Psi_n + \Psi_{n+1} + \Psi_{n-1}), \quad (7)$$

where U_0 is a parameter of the nonlinearity. Actually, Equations (6) and (7) are equations for the envelope curve of SL vibrations taken in discrete points. Such equations can be used for describing nonlinear effects and particularly dynamics of solitons in the optical SL.

SURFACE WAVES

The surface of a fluid such as water lends itself most easily to the demonstration of wave phenomena. At the same time, waves on the surface of shallow water have played a very important role in the development of nonlinear science. The entries in this encyclopedia on water waves and solitons cover this aspect. Following

narrower definitions, the term *surface waves* is often used for standing waves that form on the surface of a vessel filled with a liquid and moved up and down periodically in the direction normal to the liquid's surface. When adding the adjective *acoustic* (surface acoustic waves, SAW), one thinks of waves propagating on the surface of a solid elastic medium. These two types of surface waves will be discussed here. The former are called Faraday waves, and the most common species of the latter is named after Lord Rayleigh (John William Strutt).

Faraday Waves

In 1831, Michael Faraday reported on a series of experiments with various liquids that he made oscillate on glass plates and in a basin attached to a vibrating strip of wood (or lath) (Faraday, 1831). On the surface of the vibrating liquids, he observed the formation of standing wave patterns. With increasing amplitude of vibration, he found these standing waves to evolve into a regular square pattern (Figure 1). Faraday also noticed that the frequency of the surface waves was half of that of the driving force.

A proper mathematical explanation for the instability of the flat fluid surface, when being accelerated periodically, was given more than a century later, in 1954, by T.B. Benjamin and F. Ursell. They considered a sinusoidal acceleration with frequency ω . Let the initially planar surface be parallel to the x , y -plane and define the two-dimensional position vector $\mathbf{R} = (x, y)$. Benjamin and Ursell expanded the local excursion $\zeta(\mathbf{R}, t)$ of the surface from the planar initial position in real eigenfunctions S_m , $m = 1, 2, \dots$, of the two-dimensional Laplace operator, satisfying Neumann boundary conditions at the boundary of the fluid surface with vanishing normal derivative,

$$\zeta(\mathbf{R}, t) = \sum_m a_m(t) S_m(\mathbf{R}). \quad (1)$$

Linearizing the equations of hydrodynamics, they arrived at the Mathieu equation for the amplitudes a_m ,

$$\frac{\partial^2 a_m}{\partial t^2} = [p_m + q_m \cos(\omega t)] a_m \quad (2)$$

with coefficients q_m and p_m that depend on the corresponding eigenvalue of the Laplace operator and, hence, on the shape of the surface, on the depth of the liquid, as well as on gravity and surface tension. In addition, q_m is proportional to the amplitude of the periodic driver. The exponentially increasing solutions of the Mathieu equation that occur for certain combinations of system parameters, correspond to the instability. In particular, it becomes clear from (2) why the dominant instability is subharmonic.

The Faraday instability can thus be understood within linear theory. However, linear theory is not

Figure 1. Sequence of surface wave patterns observed by Faraday on a quadrangular pool (Faraday, 1831).

sufficient to decide on which pattern will actually form after the instability has occurred. This can be determined by application of the modern theory of pattern formation to this damped-driven system (Miles & Henderson, 1990; Zhang & Viñals, 1997). Here, the nonlinearity comes into play. For sufficiently large spatial extension of the surface, boundary conditions at the edge of the surface become unimportant, and we may expand ζ in plane waves. Near the onset of the subharmonic instability, one may write

$$\zeta(\mathbf{R}, t) = \cos(\omega t/2) \sum_{j=1}^N \exp(\mathbf{k}_j \cdot \mathbf{R}) A_j(t) + \text{c.c.} \quad (3)$$

to a good approximation. (In (3) c.c. stands for the complex conjugate and a finite number N of wave vectors has been considered.) The modulus of the wave vectors $\mathbf{k}_j$ is fixed by the dispersion relation of linear surface waves at frequency $\omega/2$. Viñals and his coworkers have shown that the slow variations of the amplitudes A_j are governed by a nonlinear equation of the form (Zhang & Viñals, 1997)

$$\frac{\partial A_j}{\partial \tau} = -\partial \mathcal{F} / \partial A_j^* \quad (4)$$

with the Lyapunov function

$$\mathcal{F} = \sum_{j=1}^N |A_j|^2 + \frac{1}{2} \sum_{j,j'=1}^N g(c_{jj'}) |A_j|^2 |A_{j'}|^2. \quad (5)$$

Here, τ is a stretched time, $c_{jj'}$ is the cosine of the angle between wave vectors $\mathbf{k}_j$ and $\mathbf{k}_{j'}$, and the function g depends on the system parameters. Stable stationary wave patterns correspond to minima of the Lyapunov function. For given system parameters, the pattern corresponding to the lowest value of $\mathcal{F}$ should be attained. Zhang and Viñals tested configurations with amplitudes $A_j, 1, \dots, M$ nonzero and $|A_j|$ independent of j , while the remaining $N - M$ amplitudes are zero. If the amplitudes corresponding to three or fewer different wave vectors are nonzero ($M \leq 3$), regular periodic patterns are obtained. The square pattern, already observed by Faraday, corresponds to two orthogonal wave vectors. With amplitudes of three different wave vectors nonzero, hexagonal or triangular patterns are generated. Interestingly, the theory of Zhang and Viñals also predicts patterns with more than three different wave vectors to be stable for certain system parameters. These correspond to quasi-periodic structures analogous to two-dimensional quasicrystals

Figure 2. Faraday wave patterns of square (a), hexagonal (b), eight-fold quasi-periodic (c), and ten-fold quasi-periodic (d) symmetry observed by Binks & van de Water (1997).

such as the Penrose tiling, for example. It has been a remarkable success of this nonlinear theory of pattern selection to predict the appearance of such quasi-periodic patterns of eight-fold (four wave vectors) and ten-fold (five wave vectors) symmetry, which have subsequently been found in experiments (Binks & van de Water, 1997) (see Figure 2).

In systems with length scales such that the boundary of the fluid's surface is relevant for the pattern formed, one has to consider the eigenfunctions $S_m(\mathbf{R})$ of the Laplace operator satisfying the correct conditions at the boundary and, hence, depending on the shape of the surface. This opens up the possibility of using Faraday waves to visualize wave-mechanical modes of stadium billiards and relating them to classical trajectories (Kudrolli et al., 2001). At high values of the periodic acceleration of the fluid, spatiotemporal chaos has been observed.

In addition to the wave patterns arising on the surface of a moving liquid, Faraday, in his 1831 report, describes two other types of standing waves on the surfaces of liquids. The first one concerns patterns that he observed when a wave-maker was oscillating right on top of the surface or partly immersed in the liquid. Ridges are formed that are directed away from the wave-maker. The second type of standing waves occurs on a sloping beach when wind is blowing along the surface against the beach. Here, the ridges are parallel to the direction of the wind. These waves have been studied in detail in theory and by further experiments (Miles & Henderson, 1990). They are relevant in the context of oceanography.

Surface Acoustic Waves

In his landmark paper of 1885, Lord Rayleigh showed that the equations of linear elasticity theory for an isotropic homogeneous elastic half-space with a planar

Figure 3. Displacements associated with a Rayleigh wave as function of depth. The surface wave is propagating in the direction of the double arrow. Displacement component normal (solid) and parallel (dashed) to the surface.

stress-free surface admit solutions that correspond to straight-crested waves propagating along the surface (Rayleigh, 1885). The deformations associated with these waves decay exponentially with depth. Such a Rayleigh wave is polarized in the plane spanned by the propagation direction and the surface normal (sagittal plane). It causes the mass elements of the solid to move on ellipses. This motion is retrograde near the surface and changes to prograde at greater depth (Figure 3).

Rayleigh himself thought of these waves in connection with earthquakes and their consequences, pointing out that surface wave amplitudes decrease more slowly with distance from the epicenter than those of bulk waves.

Since then, surface acoustic waves have found important applications in many branches of science and technology with wavelengths ranging from the kilometer scale in geophysics down to micrometers in ultrasonic nondestructive testing, acoustic microscopy, sensors, and micro-electronics. They are also used for basic research in solid-state physics with wavelengths down to the nanometer scale. The advent of the interdigital transducer on surfaces of piezoelectric media led to a number of signal processing devices based on SAW, especially frequency filters that are nowadays used in television sets and cell phones.

A distinctive feature of surface waves on solids as compared with ordinary liquids is the possibility of the medium to be anisotropic. For a long time it had not been known whether surface acoustic waves exist at all on surfaces of anisotropic media apart from special highly symmetric geometries. In the meantime, a mathematical theorem was established by Lothe and Barnett that guarantees their existence in most cases. However, generalized Rayleigh waves that occur in anisotropic media need no longer be polarized in the sagittal plane and may have more complicated depth profiles than the one shown in Figure 3. Their associated

displacement field $\mathbf{u}$ is a superposition of generalized plane waves,

$$\mathbf{u}(x, z, t) = \sum_{j=1}^n \mathbf{W}_j \exp[ik(x - vt) - |k|\alpha_j z] + \text{c.c.}, \quad (6)$$

when the wave vector $\mathbf{k} = k\hat{x}$ is along the x -direction and the elastic medium fills the half-space $z > 0$. (v is the phase velocity.) The (often complex) coefficients α_j have positive real part. In isotropic media, $n = 2$; in nonpiezoelectric media, $n \leq 3$. In very special circumstances, n may even be 1. In piezoelectric substrates, $n \leq 4$.

In anisotropic media, the group velocity of a surface acoustic wave need no longer be parallel to its wave vector. This can lead to focusing of acoustic energy propagating away from a local excitation of the surface. This effect, which is well known for acoustic bulk waves, has been demonstrated for surface waves in a comparatively simple and efficient way by Kolomenskii and Maznev. Anisotropy also gives rise to leaky waves (pseudo-surface waves) with a very high degree of localization at the surface.

When accounting for piezoelectricity and/or considering an elastic substrate in contact with other media, a whole zoo of various species of surface waves is found (Maradudin, 1985; Auld, 1990), including waves

- of shear-horizontal polarization in homogeneous piezoelectric substrates with or without metal coating (Bleustein–Gulyaev waves),
- in layered structures with shear-horizontal (Love waves) or sagittal polarization (generalized Lamb waves, Sezawa waves),
- at the interface of a solid and a liquid (Scholte waves),
- at the interface between two different solids (Stoneley waves).

The power flow associated with a Rayleigh wave is localized at the surface within a layer of approximately a wavelength. The high spatial localization favors effects generated by the elastic nonlinearity of the medium. In particular, higher harmonics are easily observed. Because neither the equations of nonlinear elasticity nor the geometry of a homogeneous half-space with a planar surface define a length scale, surface acoustic waves are nondispersive in this system. Therefore, shock formation can be observed. Theoretically, the evolution of nonlinear wave forms is studied on the basis of the following equation which follows from derivations by Lardner and Parker (Parker, 1988):

$$i \frac{\partial}{\partial \tau} B(k) = k \int_0^k F(q/k) B(q) B(k - q) dq + 2k \int_k^\infty (k/q) F^*(k/q) B(q) B^*(q - k) dq. \quad (7)$$

Figure 4. Solitary pulse shapes on the coated Si(111) surface (propagation along the [112] direction) (a,b) and on a coated surface of isotropic quartz (c). Left: Experimental results by Lomonosov and Hess (solid) and numerical simulation (dashed). Right: Stationary pulse shapes. The local slope of the surface is shown as function of arrival time. (Compiled from data published in Lomonosov et al., 2002).

Here, τ is a stretched time and the function B is the Fourier transform of the local surface slope,

$$\frac{\partial}{\partial x} u_3(x, 0, t) = \int_0^\infty B(k, \tau) \exp[ik(x - v\tau)] dk + \text{c.c.} \quad (8)$$

The complex function F depends on the second-order and third-order elastic moduli of the medium and may often be well approximated by its value at the argument $1/2$. When transforming (7) into real space, the nonlinearity turns out to be strongly nonlocal. This is the price one has to pay for eliminating the depth dependence of the displacement field from the evolution equation.

On the surface of homogeneous isotropic media, the velocity component of mass elements normal to the surface develops a cusp, while the component parallel to the surface steepens in a way similar to the pressure in the formation of shocks in gases and liquids. This behavior has been found in simulations starting with a sinusoidal wave form and in experiments with pulsed laser excitation. In order to generate acoustic pulses of high intensity at solid surfaces, this experimental technique has proven to be most effective (Lomonosov et al., 2001). A laser pulse focused on a line on the surface leads to rapid local heating and generates an explosive evaporation of a highly absorbing coating. Similar to the epicenter of an earthquake in the macroscopic world, the explosion leads to an acoustic pulse that is localized at the surface after having propagated some distance from the line of excitation.

Depositing on the substrate surface a thin film of a material different from that of the substrate leads to a linear dispersion term in (7). The evolution equation then has solitary wave solutions that may be regarded as solid state analogs of the solitons on shallow water. They have shapes strongly influenced by the anisotropy of the substrate, as demonstrated by the

examples in Figure 4. The existence of solitary surface acoustic pulses has been verified by Lomonosov and Hess using laser excitation to generate an initial pulse that subsequently evolves into a solitary pulse and a quasilinear background (Figure 4).

SYMBOLIC DYNAMICS

Dynamical systems on manifolds are usually described by equations using local Euclidean variables. Symbolic dynamics has its origins in an alternative description of the orbits of a dynamical system by Jacques Hadamard at the end of the 19th century and later by Marston Morse, where it was shown that complex orbital behavior of a dynamical system could be described using sequences of symbols (Hadamard, 1898; Morse, 1921).

A simple example that shows the usefulness of this approach is the iteration $x_{n+1} = f(x_n)$ on the interval of real numbers $\mathbb{I} = [0, 1]$ defined by a piecewise linear map

$$x_{n+1} = \begin{cases} 2x_n, & x_n < 0.5, \\ 2x_n - 1, & x_n \geq 0.5. \end{cases}$$

This map can also be described by

$$x_{n+1} = 2x_n \bmod 1$$

for $x_n \in [0, 1)$ together with $f(1) = 1$. It is easy to solve the modular equation formally for the orbital sequence $x_n = f^n(x_0)$, $0 \leq q x_0 < 1$, as

$$x_n = 2^n x_0 \bmod 1.$$

However, the formal solution is no more illuminating than the defining iteration, because it is not at all clear how the repeated exponentiation of the solution interacts with the process of reducing mod 1. To overcome this problem and unlock the dynamical secrets held within the formula, note that any real number $x \in \mathbb{I}$ can be written in the form

$$x = \sum_{n=1}^{\infty} \frac{b_n}{2^n},$$

where $b_n = 0$ or 1. Let Σ_2 denote the set of all such binary sequences. Thus, every binary sequence $\mathbf{b} = \{b_n\}_{n=1}^{\infty} \in \Sigma_2$ represents a point $\pi(\mathbf{b}) = x \in \mathbb{I}$ by a map $\pi : \Sigma_2 \rightarrow \mathbb{I}$.

Relative to this new representation of points in $\mathbb{I}$ the map f takes the form of a shift $\sigma : \Sigma_2 \rightarrow \Sigma_2$ on binary sequences as

$$\{b_1, b_2, \dots, b_n, \dots\} \mapsto \{b_2, b_3, \dots, b_{n-1}, \dots\},$$

that is,

$$\sigma(\{b_n\}_{n=1}^{\infty}) = \{b_{n+1}\}_{n=1}^{\infty}$$

simply because

$$2 \left(\sum_{n=1}^{\infty} \frac{b_n}{2^n} \right) \bmod 1 = \sum_{n=1}^{\infty} \frac{b_{n+1}}{2^n}.$$

It is easy to check that the map π provides a *semi-conjugacy* $f\pi = \pi\sigma$ for f and σ . The map π is not a conjugacy because of the redundancy in the binary representation of the reals. This can be resolved by always choosing binary sequences representing reals in $[0, 1]$ that *do not* have infinite sequences of 1s. So, for example, 0.25 has the infinite binary representations $\{010\}$ and $\{001\}$, but we choose the former. Nevertheless, the semi-conjugacy implies that for every positive integer m , $f^m\pi = \pi\sigma^m$. In particular, if $\mathbf{b} = \{b_n\} \in \Sigma_2$ is a period- m orbit of σ , then

$$f^m(\pi(\mathbf{b})) = \pi\sigma^m(\mathbf{b}) = \pi(\mathbf{b}),$$

and so π maps the σ -periodic point $\mathbf{b}$ to an f -periodic point $\pi(\mathbf{b})$. Thus, we can obtain the periodic orbits of f by investigating the periodic orbit structure of σ . But this is straightforward because the period- m periodic points of σ in Σ_2 are precisely those binary sequences

that repeat after m -digits and no fewer. Thus, period-1 points of σ are given by the repeating expansions

$$\mathbf{b} = \{\overline{0} \dots\} = \{00000 \dots\}$$

and

$$\mathbf{b} = \{\overline{1} \dots\} = \{11111 \dots\},$$

which both correspond by π to the fixed points $x = 0$ and $x = 1$, respectively, of the map f .

Period-2 points of σ are given by

$$\mathbf{b}_1 = \{\overline{01} \dots\}, \quad \mathbf{b}_2 = \{\overline{10} \dots\}.$$

Note that $\pi(\mathbf{b}_1) = \frac{1}{3}$ and $\pi(\mathbf{b}_2) = \frac{2}{3}$ and $\{\frac{1}{3}, \frac{2}{3}\}$ is the only period-2 orbit of f . We can immediately see that periodic points of all orders can be constructed for σ , and thus also for f , in this way. Points that are on *eventually* periodic orbits of f can also be obtained by delaying the introduction of the binary recurrences in the symbol sequences. Thus, any map f defined on $\mathbb{I}$ that is described by a shift on symbol sequences has a rich periodic structure. We can extract further properties about orbits of f when we observe that π can be seen as a continuous function by taking the usual Euclidean metric on $\mathbb{I}$ and the metric

$$d(\mathbf{b}, \mathbf{b}') = \sum_{n=1}^{\infty} \frac{(b_n - b'_n)}{2^n},$$

where $\mathbf{b} = \{b_n\}_{n=1}^{\infty}$ and $\mathbf{b}' = \{b'_n\}_{n=1}^{\infty}$ are elements of Σ_2 . It is now possible to consider a *topology* on Σ_2 .

A key feature of chaos is the requirement that the orbits of the map f should in some sense be bound together, thus, making the dynamics indecomposable. This can be achieved by finding an orbit of f that *densely* fills out the set $\mathbb{I}$. Such an orbit is given by constructing a sequence $\mathbf{b}$ obtained by listing all symbol sequences of length 1, then of length 2, and so on for all positive integers. Let $\mathbf{b}'$ be any prescribed binary sequence. Given any positive integer n , by construction $\mathbf{b}$ has within it the symbol block $\mathbf{b}^{(n)}$ consisting of the first n symbols of $\mathbf{b}'$. Suppose this block commences at the point b_{k+1} of $\mathbf{b}$. Then $\mathbf{b}'$ and $\sigma^k(\mathbf{b})$ have the same first n entries and thus $d(\mathbf{b}', \sigma^k(\mathbf{b})) < 2^{-n}$. The positive integer n was chosen arbitrarily, and so the orbit of $\mathbf{b}$ approaches arbitrarily close to $\mathbf{b}'$. Thus, the orbit of $\mathbf{b}$ is *dense* on $\mathbb{I}$ and binds the dynamical behavior together preventing a decomposition into closed subsets with simpler dynamical behavior.

The dense orbit was, of course, produced to a special recipe. Obviously, the orbit is not unique as other dense orbits in Σ_2 can be constructed by simple permutations of the ordering of the blocks used to construct the sequence $\mathbf{b}$. What is astonishing is that “almost all” orbits are dense. This follows from a classical result of Emil Borel around 1900 (Hardy, 1983), which, when paraphrased, says that the set of real numbers in $\mathbb{I}$, which

have all possible finite sequences of "0"s and "1"s in their binary expansions, called *normal* numbers, has full measure.

Thus, the doubling map can be described by a shift map σ on the space of symbolic sequences on two symbols, Σ_2 . The simple ideas discussed here can be extended to provide symbolic dynamics for various types of maps. The *coding* involving two or more symbols has to be carried out so that each point x of the map domain is given by a symbol string that provides the orbit of x by merely shifting the symbols (Devaney, 2003). Note that the binary sequence gives the itinerary of an orbit where if "0" represents the interval $[0, \frac{1}{2}]$ and "1" represents $[\frac{1}{2}, 1]$, the sequence gives the sequence of intervals visited by the orbit of the map f . This approach can be applied to a wide class of one-dimensional maps (Guckenheimer, 1979; Guckenheimer et al., 1977), but it also has much greater importance in dynamical systems.

A key dynamical construction is the *Smale Horseshoe* (Smale, 1967). The simplest example is a diffeomorphism h of the square $Q \in \mathbf{R}^2$ whose image in $\mathbf{R}^2$ is folded in the shape of a horseshoe to overlay the square. The map h has an invariant Cantor set $\Lambda \subset Q$ such that $h|\Lambda$ can also be coded with *bi-infinite* binary sequences together with a shift map. This results in a complex periodic orbit structure and dense orbits within Λ , which gives some of the ingredients of chaos. The key components of the set Λ are the *homoclinic* points, that is, those points that asymptotically approach a periodic orbit of h in both forward and reverse iterations.

The Smale–Birkhoff Theorem proves that "folding maps" of this type, and the associated complex dynamical behavior, exist in the neighborhood of such homoclinic points. This is precisely stated as follows (Smale, 1967).

Theorem. Let f be a Kupka–Smale diffeomorphism of a compact manifold M and $x^\dagger$ be a transverse homoclinic point of a periodic point x^* of f . Then there is a closed subset Λ containing $x^\dagger$, such that (i) Λ is a Cantor set; (ii) $f^p(\Lambda) = \Lambda$ for some $p \in \mathbf{Z}^+$; and (iii) $f^p|\Lambda$ is topologically conjugate to a shift on a symbol space.

Note that all possible binary sequences are allowed in the above symbol spaces and, thus, we have been considering *full* shifts. In many practical applications of data storage, there are practical restrictions on the stored patterns of sequences. The problem of transferring codes that satisfy one set of constraints into other restricted symbol sets involve *sub-shifts of finite type* and allow applications to communications coding and algebra (Coornaert & Papadopoulos, 1993; Lind & Marcus, 1996; Kitchens, 1997). Symbolic coding has been directly useful in modeling in engineering and biology, see (Daw et al., 1997) and (Voss et al., 2000).

SYMMETRY BREAKING

See Bifurcations

SYMMETRY GROUPS

Mathematically, a group is a set G together with a pair-wise "group multiplication" on elements of G that satisfies the following axioms. (i) Multiplication is associative, meaning that $xy(z) = x(yz)$ for x ,

y , and z any elements of G . (ii) G contains an identity element e for which $ex = x = xe$ where x is any element of G . (iii) Each element of G has an inverse (x^{-1}), satisfying $x^{-1}x = e = xx^{-1}$ (Armstrong, 1988; Birkhoff & MacLane, 1953). Groups for which all of the multiplications commute are said to be abelian.

Easily visualized examples of finite symmetry groups are provided by operations on familiar geometrical objects, such as squares, hexagons, cubes, and tetrahedrons, which carry vertices into themselves. In general, there will be a finite set of f linearly independent functions (in the space of the geometrical object) that are carried into linear combinations of themselves by the group operations. Thus, each group element corresponds to a matrix, and the corresponding set of $f \times f$ matrices is called a representation of the group (Landau & Lifschitz, 1958).

For a square that is lying on the plane with its center at the origin, group elements are rotations about the origin (by 90° , 180° , and 270°) and reflections (in horizontal and vertical axes and in the two diagonals). Group multiplication is defined as performing two operations in order, and the identity element leaves all vertices unchanged. The reader may find it helpful to cut out a square of cardboard, number the four corners, and construct a group multiplication table for these eight elements, noting that it is not abelian.

It has long been known that symmetries of a dynamic system influence the nature of possible characteristic solutions or natural modes of behavior (See **Symmetry: equations vs. solutions**). To appreciate this restriction, consider a system with reflection symmetry, and note that any solution can be resolved into two components that are respectively symmetric and antisymmetric about the plane of symmetry. In a linear system, the symmetric and antisymmetric components do not interact; thus, modes must be either symmetric or antisymmetric about the plane. In a nonlinear system, however, there can also be natural modes of behavior that are neither symmetric nor antisymmetric. Such symmetry breaking is a fundamental feature of nonlinear dynamic systems, leading to the formation of solitons on optical fibers, impulses on nerve axons, and local modes in chemical molecules and molecular crystals.

Applications to Physical Chemistry

A typical chemical molecule is a simple geometric structure for which a symmetry group multiplication table has a finite number of entries (Herzberg, 1991; Wilson et al., 1980). Thus, the water molecule (H_2O) has a single reflection plane; methane (CH_4) is described by the same symmetry group as the regular tetrahedron, benzene (C_6H_6) by a planar hexagon, and so on. The physical chemist uses these finite symmetry groups to organize measurements of electronic and

vibrational spectra, using the following notations: reflection group (σ), n -fold rotation symmetry (C_n), inversion symmetry (I), tetrahedral symmetry (T), and so on. A particularly lucid introduction to point symmetry notations is given by Landau & Lifschitz (1958).

Because quantum theory is linear, vibrational and electronic wave functions have the following property. If n successive applications of a symmetry operation return a molecule to its original orientation, the amplitude of the corresponding quantum wave function must change by an n th root of unity under the same operation. Under reflections, in other words, amplitudes change by factors of either $+1$ or -1 (symmetric or antisymmetric), whereas CH-stretching modes of benzene (C_6) change under rotations of 60° by factors of $\exp(\pm im\pi/3)$, where $m = 0, \pm 1, \pm 2, \pm 3, \pm 4$, or ± 5 . Physical chemists label their spectral lines with notations that correspond to these factors (Landau & Lifschitz, 1958).

Although molecular vibrations can be quite nonlinear (especially those involving hydrogen atoms), this nonlinearity does not play a role in transitions from the ground state to first quantum levels of small molecules. (This is because the nonlinear operator of lowest order contains a product of two lowering operators, which annihilates first quantum states.) Thus, the excitations to the first quantum level are governed by linear symmetry considerations, and local modes in molecules are observed only for transitions to higher quantum levels.

The linear modes of a molecule with a center of inversion (I) appear either in infrared absorption or Raman scattering measurements, but not both. This "principle of mutual exclusion" helps to sort out the components of linear vibrational spectra. Local modes, which are nonlinear, can appear in both infrared and Raman measurements.

A periodic solid (or molecular crystal) with periodic boundary conditions can be viewed as a very large molecule, for which the number of elements of the corresponding symmetry group is also very large. Of particular interest are translations by lattice constants (a , b , and c) along the crystal axes, which bring the crystal back to its original configuration. The phase shift of an electronic or vibrational wave function under such a translation is $\exp(ik)$, where k is called the crystal momentum. As the number of unit cells in the model approaches infinity, the three components of k vary, respectively, from $-\pi/a$ to π/a , $-\pi/b$ to π/b , and $-\pi/c$ to π/c . In vibrational modes of such systems, nonlinearity can arise from local lattice distortion, which allows symmetry breaking (local mode formation) to be observed at the first quantum level.

Applications to Field Theories

The above definition of a group does not require the number of group elements to be finite, and many partial

differential equations provide examples of infinite-order symmetry groups.

The sine-Gordon (SG) equation, for example, is invariant under the independent variable transformation $(x, t) \rightarrow (\xi, \tau)$, where $\xi = (x - vt) / \sqrt{1 - v^2}$ and $\tau = (t - vx) / \sqrt{1 - v^2}$. Taking this invariance as the property defining elements of the group, a symmetry group comprises all such transformations, parameterized by the continuous variable v with $|v| < 1$. This is a one-dimensional version of the Lorentz transformation, which is shared by Maxwell's equations. Interestingly, if $u(x)$ is a time-independent solution of SG, then $u[(x - vt) / \sqrt{1 - v^2}]$ is also a solution that demonstrates Lorentz contraction (becomes smaller as $v \rightarrow 1$).

In 1915, Emmy Noether established the following important result on the application of symmetry groups to field theories (José & Saletan, 1998).

Noether's theorem. *If a system is described by a Lagrangian that remains invariant under some continuous symmetry transformation, then there is a corresponding conservation law and constant of the motion.*

This theorem has immediate implications. As fundamental descriptions of nature are assumed to be Lagrangian and independent of time displacements (the science of today is the same as it was yesterday), the corresponding conserved quantity is energy. In other words, the law of energy conservation stems from time invariance of scientific laws. Similarly, conservation of momentum and conservation of angular momentum arise, respectively, from the assumptions that scientific laws are independent of spatial displacements and angles of rotation.

Nowadays, it is widely assumed that the fundamental fields of nature are derived from a Lorentz invariant Lagrangian density or more generally based on the Poincaré group, which incorporates independence with respect to displacements in time and space (Kim & Noz, 1986). As physicists attempt to formulate a fundamental description of nature, they use Noether's theorem to build in additional constants (charge, spin, rest mass, etc.) that have been empirically observed.

The pure soliton equations (Korteweg-de Vries, nonlinear Schrödinger, sine-Gordon, and so on) are Lagrangian systems that each have a countably infinite number of conservation laws and constants of the motion. It would be interesting to better understand the corresponding symmetries.

SYMMETRY: EQUATIONS VS. SOLUTIONS

The importance of symmetries in various fields of science is well appreciated, much beyond the scope of this entry. Here we focus on one particular aspect—how knowledge about discrete symmetry operations allows one to conclude certain properties of solutions of differential equations.

Let us start with one of the simplest examples: one oscillator that is governed by the equation

$$\frac{d^2x}{dt^2} = -\frac{dV(x)}{dx}, \quad (1)$$

where t is time, x the coordinate of the oscillator, and $V(x)$ its nonnegative potential with $V(0) = 0$. All solutions to this equation are time-periodic. If an equation is invariant under a certain symmetry operation, then the same symmetry operation applied to a solution of the equation either generates a new solution or reproduces the same old solution it is then said that the solution is also invariant.

All symmetries considered below, in fact, do not change the energy of the oscillator; thus, the solution is always invariant up to a trivial shift of the origin of time $t \rightarrow t + t_0$. One symmetry that leaves Equation (1) invariant is time reversal $t \rightarrow -t$, which implies that for each solution the origin of time can be chosen in such a way that the solution is also invariant under time reversal, that is, $x_s(t) = x_s(-t)$. For practical purposes, it means that numerical expansions of solutions into Fourier series may be restricted to cosine Fourier series. Another symmetry may hold if $V_s(x) = V_s(-x)$. Then the equation is invariant under space reflection $x \rightarrow -x$.

In order to invert the sign of a periodic function $x(t)$, we may assume either antisymmetry $x_a(t) = -x_a(-t)$ or shift symmetry $x_{sh}(t) = -x_{sh}(t + T/2)$ where T

is the period. Thus, for symmetric potentials, $x(t)$ is symmetric in time, antisymmetric in time (around a different origin), and shift symmetric. In particular, this implies that all even components of the Fourier expansion of this function vanish, including the dc component.

Consider next a more sophisticated model of a particle subject to a space-periodic force $f(x) = -dV/dx$ (period λ) and a time-periodic field $E(t)$ (period T) with zero mean:

$$\frac{d^2x}{dt^2} = f(x) + E(t). \quad (2)$$

Equation (2) corresponds to a non-integrable system with 1.5 degrees of freedom (a three-dimensional phase space). The more complicated the equations become, the more symmetries one might consider. Assume symmetry operations that change the sign of the velocity $v = dx/dt$. There are two symmetries: time reversal $t \rightarrow -t$ if $E(t) \equiv E_s(t)$ and a combined space reflection with time shift one $x \rightarrow -x$, $t \rightarrow t + T/2$ if $f(x) \equiv f_a(x)$, $E(t) \equiv E_{sh}(t)$. For both symmetries to be valid, certain properties of the functions f and E are required. In particular, the time-periodic field $E(t)$ (e.g., an ac electric field) enters both symmetry requirements. That means that by choosing an $E(t)$ dependence that is neither symmetric nor shift symmetric, we lose both symmetries. What are the consequences?

Note first that due to the non-integrability of (2), the separatrix for $E=0$ is replaced by a chaotic or stochastic layer in the phase space. Ergodicity inside the layer implies that the time average of a certain quantity over a trajectory, if existing, does not depend on the concrete trajectory choice. Returning to the above symmetries and choosing the time average of the velocity of the particle, we conclude that (i) the velocity average exists because the stochastic layer is bounded, and (ii) if the average velocity is nonzero for one trajectory from the stochastic layer and if any of the above symmetries apply, the velocity average will be opposite for a corresponding symmetry related trajectory from the same stochastic layer—with the only consequence that the average velocity vanishes exactly. However, choosing an $E(t)$ dependence that violates both symmetry requirements, we may expect that the average velocity of any trajectory inside the stochastic layer will become nonzero. In other words, we can predict how to generate a dc current of many non-interacting particles by a symmetry breaking choice of the field $E(t)$. This has been, indeed, predicted and demonstrated theoretically and numerically (Flach et al., 2000) and verified experimentally for directed diffusion of ultracold rubidium atoms in symmetric optical lattices (Schiavoni et al., 2003).

Next, consider applications of the above concepts to systems that are characterized by the presence of

dissipation and fluctuations. Usual additive Gaussian white noise terms possess all symmetries of periodic functions; that is, if $\xi(t)$ is a realization of a stochastic process, so is $\xi(-t)$, $\xi(t + \tau)$, $-\xi(t)$, and so on. When starting with a corresponding Langevin type equation

$$\frac{d^2x}{dt^2} = f(x) + E(t) - \gamma \frac{dx}{dt} + \xi(t), \quad (3)$$

it is then possible to drop the noise term and study the symmetries of the deterministic yet dissipative equation

$$\frac{d^2x}{dt^2} = f(x) + E(t) - \gamma \frac{dx}{dt}. \quad (4)$$

While the strategy of the analysis is similar to the one outlined above, for the case of zero dissipation $\gamma=0$, the phase space of Equation (4) is again three-dimensional, but is now composed of basins of attraction with each basin corresponding to a certain attractor. Existing symmetries of the equation imply symmetry relationships between attractors and their basins of attraction. Violation of symmetries of the equations implies desymmetrization of basins of attraction of (previously symmetry related) attractors. Thus, adding again the stochastic noise to return to the starting Equation (3), intuition suggests that the noise when leading to an average over various basins of attraction will either make certain averages vanish (in the presence of symmetries) or not vanish (in the absence of symmetries). Special care is required due to the fact that some symmetries of (4) may relate attractors with repellers. Another approach is to consider partial differential equations for the probability distributions and their symmetry properties (see Denisov et al., 2002).

The above approach has been successfully used to predict such diverse phenomena as rectification of heat currents (Flach et al., 2002) and induction of magnetizations (Flach & Ovchinnikov, 2000). Finally, note that it is easier to predict a nonzero average by breaking symmetries than to obtain an understanding for the concrete microscopic mechanisms of symmetry breaking and thus to obtain reliable estimates for the expected quantity of rectification and its dependence on essential parameters of the system (Reimann, 2002).

SYMPLECTIC MAPS

First used mathematically by Hermann Weyl, the term *symplectic* arises from a Greek word that means “twining or plaiting together.” This is apt, as symplectic systems always involve a pair of n -dimensional variables, the configuration q , and momentum p , which are intertwined by the symplectic two form

$$\omega = dp \wedge dq. \tag{1}$$

This antisymmetric, bilinear form acts on a pair of tangent vectors and computes the sum of the areas of the parallelograms formed by projecting the vectors onto the planes defined by each canonical pair (q_i, p_i) , $i = 1, \dots, n$, giving

$$\omega(v, w) = \sum_{i=1}^n (v_{p_i} w_{q_i} - v_{q_i} w_{p_i}).$$

A diffeomorphism $f : X \rightarrow X$ on a $2n$ -dimensional manifold X with coordinates $z = (q, p)$ is symplectic if it preserves the symplectic form, that is, if $f^* \omega = \omega$ (Arnol’d, 1989; McDuff & Salamon, 1995). If we write $z' = (q', p') = f(q, p)$, the symplectic condition becomes

$$Df^t J Df = J, \quad \text{where } J = \begin{pmatrix} 0 & I \\ -I & 0 \end{pmatrix}. \tag{2}$$

Here $Df_{ij} = \partial f_i / \partial z_j$ is the Jacobian matrix of f , J is the Poisson matrix, and I is the $n \times n$ identity matrix. Equivalently, Stokes’ theorem can be used to show that the loop action, $A[\gamma] = \oint_\gamma p dq$, is preserved by f for any contractible loop γ on X . If f preserves the loop action for all loops, even those that are not contractible, then it is *exact symplectic*.

When $n = 1$, the symplectic condition is equivalent to $\det(Df) = 1$, so that the map is area- and orientation-preserving. Examples include the much studied *standard map* and the area-preserving Hénon quadratic map $f(q, p) = (p + a - q^2, -q)$ (Meiss, 1992). When $n > 1$, the symplectic condition implies volume and orientation preservation, but as we will see, it is stronger than this. A generalization of the standard map to higher dimensions is the map

$$\begin{aligned} q' &= q + p - \nabla V(q), \\ p' &= p - \nabla V(q), \end{aligned} \tag{3}$$

where $q \in \mathbb{T}^n$ is an angle, $p \in \mathbb{R}^n$ is its conjugate momentum, and $V(q)$ is a periodic potential. This map is exact symplectic for any V . Beginning in 1972, Claude Froeschlé studied the case $n = 2$ and $V(q) = a \cos q_1 + b \cos q_2 + c \cos(q_1 + q_2)$. Similarly, the natural generalization of the Hénon map is the quadratic symplectic map whose normal form has been given by Moser (1994).

Applications

Symplectic maps arise from Hamiltonian dynamics, because these preserve the loop action. Thus, for example, the time t map of any Hamiltonian flow is symplectic, as is a Poincaré return map defined on a cross section. It is often easier to study the Poincaré map instead of the flow, because the dimension is reduced. Even though explicit construction of the map is typically impossible, approximation methods often suffice.

For example, the time T map of a periodically forced system $H(q, p, t) = H(q, p, t + T)$, such as a pendulum with an oscillating support, is symplectic (See **Hamiltonian systems**). An extreme example is $H = \frac{1}{2} p^2 - k \cos(q) \delta(t)$, where δ is the periodic Dirac delta function; the corresponding map is the standard map.

As Birkhoff showed, an ideal billiard (a free particle moving inside a rigid, convex table) is naturally written as a symplectic map. The canonical coordinates are the position and the tangential momentum at a collision point. Symplectic maps also arise naturally in systems where the forces are localized in time or space. For example, a circular particle accelerator or storage ring has a sequence of accelerating and focusing elements that can be modeled by a composition of symplectic maps, providing the damping effects of radiation can be neglected (Forest, 1998).

Area-preserving maps also arise in the study of the motion of Lagrangian tracers in incompressible fluids or of particles tightly gyrating around magnetic field lines. In particular, when one component of the field is particularly strong, such as in the plasma device called a tokamak, the transverse dynamics reduces to an area-preserving map.

Autonomous canonical transformations are symplectic maps. For example, if $F(q, q')$ is a generating function for a canonical transformation, then it generates a symplectic map. In particular, the Froeschlé map (3) is generated by $F(q, q') = \frac{1}{2} (q' - q)^2 - V(q)$.

An algorithm that respects the symplectic nature of Hamiltonian dynamics is called a symplectic integrator. A first-order symplectic algorithm with time step Δt for the Hamiltonian $H(q, p)$ is generated by $F(q, p') = qp' + \Delta t H(q, p')$, where

$dF = q'dp' + pdq$, giving the map

$$q' = q + \Delta t \frac{\partial H}{\partial p'}(q, p'), \quad p' = p - \Delta t \frac{\partial H}{\partial q}(q, p'). \quad (4)$$

Note that the map is implicit because H is evaluated at p' . However, for the case that $H = K(p) + V(q)$ this becomes a leap-frog Euler scheme, an example of a “splitting” method. Symplectic versions of many standard algorithms—such as Runge–Kutta—can be obtained (Marsden et al., 1996). While there is still some controversy on the utility of symplectic methods versus methods that, for example, conserve energy and other invariants or have variable time-stepping, they are superior for stability properties because they respect the spectral properties of the symplectic group.

The Symplectic Group

The stability of an orbit $\{...z_t, z_{t+1}, ...\}$, where $z_{t+1} = f(z_t)$, is governed by the Jacobian matrix of f evaluated along the orbit, $M = \prod_t Df(z_t)$. When f is symplectic, M obeys (2), $M^t J M = J$. The set of all such $2n \times 2n$ matrices form the symplectic group $Sp(2n)$. This group is an $n(2n+1)$ -dimensional Lie group, whose Lie algebra is the set of Hamiltonian matrices—matrices of the form JS where S is symmetric. Thus, every near-identity symplectic matrix can be obtained as the exponential of a Hamiltonian matrix and corresponds to the time t -map of a linear Hamiltonian flow. There are symplectic matrices, however, that are not the exponentials of Hamiltonian matrices; for example, $-I$. As a manifold, the symplectic group has a single nontrivial loop (its fundamental group is the integers). The winding number of a loop in the symplectic group is called the Maslov index (McDuff & Salamon, 1995); it is especially important for semi-classical quantization.

If M is a symplectic matrix and λ is an eigenvalue of M with multiplicity k , then so is λ^{-1} . Moreover $\det(M) = 1$, so M is volume and orientation preserving. A consequence of this spectral theorem is that orbits of a symplectic map cannot be asymptotically stable. There are four basic stability types for symplectic maps: an eigenvalue pair (λ, λ^{-1}) is

- *hyperbolic*, if λ is real and larger than one;
- *hyperbolic with reflection*, if λ is real and less than minus one;
- *elliptic*, if $\lambda = e^{2\pi i \omega}$ has magnitude one;
- part of a *Krein quartet*, if λ is complex and has magnitude different from one, for then there is a quartet of related eigenvalues $(\lambda, \lambda^{-1}, \bar{\lambda}, \bar{\lambda}^{-1})$.

Thus, a periodic orbit can be linearly stable only when all of its eigenvalue pairs are elliptic. For this case, the linearized motion corresponds to rotation with n rotation numbers ω_i .

Symplectic Geometry

Every symplectic map is volume- and orientation-preserving, but the group $\text{Symp}(X)$ of symplectic diffeomorphisms on X is significantly smaller than that of the volume-preserving ones. This was first shown in 1985 by Gromov in his celebrated “nonqueezing” (or symplectic camel) theorem. Let $B(r)$ be the closed ball of radius r in $\mathbb{R}^{2n}$ and $C_1(R) = \{(q, p) : q_1^2 + p_1^2 \leq R^2\}$ be a cylinder of radius R whose circular cross section is a symplectic plane. Because the volume of C_1 is infinite, it is easy to construct a volume-preserving map that takes $B(r)$ into $C_1(R)$ regardless of their radii. What Gromov showed is that it is impossible to do this symplectically whenever $r > R$. This is one example of a *symplectic capacity*, leading to a theory of symplectic topology (McDuff & Salamon, 1995).

Another focus of this theory is to characterize the number of fixed points of a symplectic map, that is, to generalize the classical Poincaré–Birkhoff theorem for area-preserving maps on an annulus. Arnol'd conjectured in the 1960s that any Hamiltonian diffeomorphism on a compact manifold X must have at least as many fixed points as a function on X must have critical points. A Hamiltonian map is a symplectic map that can be written as a composition of maps of the form (4). Conley and Zender proved this in 1985 for the case that X is the $2n$ -torus: f must have at least $2n+1$ fixed points (at least 2^{2n} if they are all nondegenerate) (Golé, 2001).

Dynamics

In general, the dynamics of a symplectic map consists of a complicated mixture of regular and chaotic motion (Meiss, 1992). Numerical studies indicate that the chaotic orbits have positive Lyapunov exponents and fill sets of positive measure that are fractal in nature. Regular orbits include periodic and quasi-periodic orbits. The latter densely cover invariant tori whose dimensions range from 1 to n . Near elliptic periodic orbits, the phase space is foliated by a positive-measure cantor set of n -dimensional invariant tori. There are chaotic regions in the *resonant* gaps between the tori, but the chaos becomes exponentially slow and exponentially small close to the periodic orbit. Some of these observations, but not all, can be proved.

The simplest case is that of an integrable symplectic map, which can be written in Birkhoff normal form: $f(\theta, J) = (\theta + \nabla S(J), J)$. Here (θ, J) are angle-action coordinates (each n -dimensional) and $\Omega = \nabla S$ is the rotation vector. Orbits for this system lie on invariant tori; thus, the structure is identical to that for integrable Hamiltonian systems.

The Birkhoff normal form is also an asymptotically valid description of the dynamics in the neighborhood of a nonresonant elliptic fixed point, one for which

$m \cdot \Omega(0) \neq n$ for any integer vector m and integer n . However, the series for the normal form is not generally convergent. Nevertheless, KAM theory implies that tori with Diophantine rotation vectors do exist near enough to the elliptic point, providing the map is more than C^3 and that the twist, $\det D\Omega(0)$, is nonzero. Each of these tori is also a Lagrangian submanifold (an n -dimensional surface on which the restriction of the symplectic form (1) vanishes). The relative measure of these tori approaches one at the fixed point.

Nevertheless, the stability of a generic, elliptic fixed point is an open question. Arnol'd showed by example in 1963 that lower-dimensional tori can have unstable manifolds that intersect the stable manifolds of nearby tori and thereby allow nearby trajectories to drift "around" the n -dimensional tori; this phenomenon is called Arnol'd diffusion (Lochak, 1993). When the map is analytic, the intersection angles become exponentially small in the neighborhood of the fixed point, and the existence of connections becomes a problem in perturbation theory *beyond all orders*.

Aubry–Mather theory gives a nonperturbative generalization of KAM theory for the case of monotone twist maps when $n = 1$. These are symplectic diffeomorphisms on the cylinder $\mathbb{S} \times \mathbb{R}$ (or on the annulus) such that $\partial q' / \partial p > c > 0$. For this case, Aubry–Mather theory implies that there exist orbits for all rotation numbers ω . When ω is irrational, these orbits lie on a *Lipschitz graph*, $p = P(q)$, and their iterates are ordered on the graph just as the iterates of the uniform rotation by ω . They are either dense on an invariant circle or an invariant Cantor set (called a *cantorus* when discovered by Percival). These orbits are found using a Lagrangian variational principle and turn out to be global minima of the action.

Aubry–Mather theory can be partially generalized to higher dimensions, for example, to the case of rational rotation vectors, where the orbit is periodic (Golé, 2001). Moreover, Mather (1991) has shown that action-minimizing invariant measures exist for each rotation vector, though they are not necessarily dynamically minimal. The existence of invariant cantor sets with any incommensurate rotation vector can also be proven for symplectic maps near an anti-integrable limit (MacKay & Meiss, 1992). Finally, converse KAM theory, which gives parameter domains where there are no invariant circles for the standard map, implies that, for example, the Froeschlé map has no Lagrangian invariant tori outside a closed ball in the space of its parameters (a, b, c) (MacKay et al., 1989).

SYNCHRONIZATION

In a classical context, synchronization means adjustment of rhythms of self-sustained periodic oscillators due to their weak interaction, which can be described in terms of phase locking and frequency entrainment. The modern concept also covers such objects as rotators and chaotic systems, in which one distinguishes between different forms of synchronization, including complete, phase, and master–slave.

The history of synchronization goes back to the 17th century when the Dutch scientist Christiaan Huygens reported on his observation of synchronization of two pendulum clocks, which he had invented shortly before (Hugenii, 1673).

... It is quite worth noting that when we suspended two clocks so constructed from two hooks imbedded in the same wooden beam, the motions of each pendulum in opposite swings were so much in agreement that they never receded the least bit from each other and the sound of each was always heard simultaneously. Further, if this agreement was disturbed by some interference, it reestablished itself in a short time. For a long time I was amazed at this unexpected result, but after a careful examination finally found that the cause of this is due to the motion of the beam, even though this is hardly perceptible. The cause is that the oscillations of the pendula, in

proportion to their weight, communicate some motion to the clocks. This motion, impressed onto the beam, necessarily has the effect of making the pendula come to a state of exactly contrary swings if it happened that they moved otherwise at first, and from this finally the motion of the beam completely ceases. But this cause is not sufficiently powerful unless the opposite motions of the clocks are exactly equal and uniform.

Despite being among the oldest scientifically studied nonlinear effects, synchronization was understood only in the 1920s when Edward Appleton and Balthasar van der Pol theoretically and experimentally studied synchronization of triode oscillators.

The synchronization properties of periodic self-sustained oscillators are based on the existence of a special variable, phase ϕ . Mathematically, ϕ can be introduced as the variable parametrizing motion along the stable limit cycle in the state space of an autonomous continuous-time dynamical system. One can always choose phase in a way that it grows uniformly in time,

$$\frac{d\phi}{dt} = \omega_0, \quad (1)$$

where ω_0 is the natural frequency of oscillations. The phase is neutrally stable, meaning that its perturbations neither grow nor decay. This corresponds to the invariance of solutions of autonomous dynamical systems with respect to time shifts. Thus, a small perturbation (for example, an external periodic forcing or coupling to another system) can cause large deviations of the phase—contrary to the amplitude, which is only slightly perturbed due to the transversal stability of the cycle. This property allows description of the effect of small forcing/coupling via the phase approximation.

Considering the simplest case of a limit cycle oscillator driven by a periodic force with frequency ω and amplitude ε , one can write the equation for the perturbed phase dynamics in the form

$$\frac{d\phi}{dt} = \omega_0 + \varepsilon Q(\phi, \omega t), \quad (2)$$

where the coupling function Q is 2π -periodic in both its arguments and depends on the form of the limit cycle and the forcing. Close to the resonance $\omega \approx \omega_0$, the function Q contains fast oscillating and slow varying terms, the latter can be written as $q(\phi - \omega t)$. Upon averaging over a cycle, one obtains the following basic equation for the phase dynamics

$$\frac{d\Delta\phi}{dt} = -(\omega - \omega_0) + \varepsilon q(\Delta\phi), \quad (3)$$

where $\Delta\phi = \phi - \omega t$ is the difference between the phases of the oscillations and of the forcing. The function q is 2π -periodic, and in the simplest case $q(\cdot) = \sin(\cdot)$ Equation (3) is called the Adler equation.

One can see that on the plane of parameters of the external forcing, there is a region

Figure 1. (a) A sketch of Arnol'd tongues. (b) Devil's staircase for a fixed amplitude of the forcing (dashed line in (a)).

($\varepsilon q_{\min} < \omega - \omega_0 < \varepsilon q_{\max}$) where Equation (3) has a stable stationary solution that exactly corresponds to phase locking (the phase ϕ just follows the phase of the forcing, so $\phi = \omega t + \text{constant}$) and frequency entrainment (the observed frequency of the oscillator $\Omega = \langle \dot{\phi} \rangle$ exactly coincides with the forcing frequency ω). Everyday examples of synchronization by external forcing are radio-controlled clocks, cardiac pacemakers, and circadian systems (the internal clocks of living objects that are synchronized to the exact 24-h periodic rhythm of sunlight).

Generally, synchronization is also observed for higher-order resonances $n\omega \approx m\omega_0$. In this case, the dynamics of the generalized phase difference $\Delta\phi = m\phi - n\omega t$ is described by an equation similar to Equation (3), namely, by $d(\Delta\phi)/dt = -(n\omega - m\omega_0) + \varepsilon \bar{q}(\Delta\phi)$. The term *synchronous regime* then means perfect entrainment of the oscillator frequency at the rational multiple of the forcing frequency, $\Omega = n\omega/m$, as well as phase locking $m\phi = n\omega t + \text{constant}$. The overall picture can be shown on the (ω, ε) plane, where a family of triangular-shaped synchronization regions exists touching the ω -axis at the rationals of the natural frequency $m\omega_0/n$. These regions are called "Arnol'd tongues" (see Figure 1a). This picture is preserved for moderate forcing, although now the shape of the tongues generally differs from being exactly triangular.

For a fixed amplitude of the forcing ε and variable driving frequency ω , one observes different phase locking intervals where the motion is periodic, whereas in between them it is quasi-periodic. The curve Ω vs. ω , thus, consists of horizontal plateaus at all possible rational frequency ratios; this fractal curve is called a "devil's staircase" (Figure 1b).

An experimental example of such a curve is the voltage-current plot for a Josephson junction in an ac electromagnetic field, where synchronization plateaus are called Shapiro steps. As a junction can be considered as a rotator (rotations are maintained by a dc current), this example demonstrates that synchronization properties of rotators are very close to those of oscillators.

Synchronization of two coupled self-sustained oscillators can be described in a similar way. A weak interaction affects only the phases of two oscillators ϕ_1 and ϕ_2 , and Equation (1) generalizes to

$$\begin{aligned}\frac{d\phi_1}{dt} &= \omega_1 + \varepsilon Q_1(\phi_1, \phi_2), \\ \frac{d\phi_2}{dt} &= \omega_2 + \varepsilon Q_2(\phi_2, \phi_1).\end{aligned}\quad (4)$$

For the phase difference $\Delta\phi = \phi_2 - \phi_1$, one obtains after averaging an equation of the type of (3). Synchronization now means that two non-identical oscillators start to oscillate with the same frequency (or, more generally, with rationally related frequencies). This common frequency usually lies between ω_1 and ω_2 . Note that locking of the phases and frequencies implies no restrictions on the amplitudes, in fact, the synchronized oscillators may have very different amplitudes and wave forms; for example, oscillations may be relaxation (integrate-and-fire) or quasiharmonic.

The mutual synchronization in a large population of oscillators (the Kuramoto transition in a population of globally coupled phase oscillators, for example) can be treated as a nonequilibrium phase transition—the mean oscillating field serving as an order parameter. Examples of synchronization in large ensembles include rhythmic applause and simultaneous flashing of fireflies, adjustment of menstrual cycles in women's dormitories, and so on. Synchronization in lattices of coupled self-sustained oscillators usually sets in via formation of clusters, that is, groups of oscillators (neighbors in a lattice) having the same frequency, and with increase of coupling the clusters grow and merge.

The concept of synchronization has been extended to include chaotic systems. One effect, called phase synchronization, is mostly close to the classical locking phenomena. Indeed, many chaotic self-sustained oscillators admit determination of the instantaneous phase and the corresponding mean frequency. Often one can find a projection of the strange attractor that looks like a smeared limit cycle, so phase is then introduced as a variable that gains 2π with each rotation. These rotations are non-uniform due to chaos, which can be modeled by an effective noise in phase dynamics. If this noise is small (i.e., the rotations are rather uniform), the mean frequency of the system can be entrained by a periodic forcing while the chaos is preserved. If two or more chaotic oscillators with different natural frequencies interact, their mean frequencies can be adjusted while the amplitudes remain chaotic and only weakly correlated.

Another type of chaotic synchronization—complete synchronization—can be observed for identical chaotic systems of any type (maps, autonomous or driven time-continuous systems). In the simplest case of

two diffusively coupled in all variables systems, the dynamics is described by

$$\begin{aligned}\frac{dx}{dt} &= \mathbf{F}(x) + \varepsilon(\mathbf{y} - x), \\ \frac{dy}{dt} &= \mathbf{F}(\mathbf{y}) + \varepsilon(\mathbf{x} - \mathbf{y}),\end{aligned}\quad (5)$$

where ε is the coupling parameter. The regime when $\mathbf{x}(t) = \mathbf{y}(t)$ for all t is called complete synchronization; because in this state the diffusive coupling vanishes, the dynamics is the same as if the systems were uncoupled. Although such symmetric solution exists for all ε , it is stable only if the coupling is sufficiently strong. To find the critical value of the coupling, one linearizes Equations (5) near the synchronized state and obtains for the mismatch $\mathbf{v}(t) = \mathbf{y}(t) - \mathbf{x}(t)$, the linearized system

$$\frac{d\mathbf{v}}{dt} = J(t)\mathbf{v} - 2\varepsilon\mathbf{v},\quad (6)$$

where $J(t)$ is the Jacobian at the chaotic solution $\mathbf{x}(t)$. The ansatz $\mathbf{v} = e^{-2\varepsilon t}\mathbf{u}$ removes the last term on the right-hand side of (6), and the resulting equation coincides with the linearized equation for small perturbations of the solutions of an individual chaotic oscillator. Thus, $\mathbf{u}$ grows in proportion to the maximum Lyapunov exponent λ of a single system, and the critical coupling is $\varepsilon_c = \lambda/2$. Complete synchronization occurs if $\varepsilon > \varepsilon_c$, that is, when the divergence of trajectories of interacting systems due to chaos is suppressed by the diffusive coupling. For weak coupling $\varepsilon < \varepsilon_c$, the states of two systems are different, $\mathbf{x}(t) \neq \mathbf{y}(t)$. Some other forms of synchronization in chaotic systems (generalized, master–slave) are similar to the complete one, and in all these cases synchronization appears if the coupling is strong enough.

SYNERGETICS

Synergetics deals with the spontaneous formation of spatiotemporal or functional structures in complex open systems by means of self-organization. The word *synergetics* is taken from Greek and means "science of cooperation." The central aim of synergetics, comprising both theoretical and experimental studies, is the search for basic principles that govern self-organization in both the physical and life sciences. To this end, a comprehensive mathematical theory has been developed that comprises both deterministic and stochastic processes.

Historical Background

Synergetics was initiated by Hermann Haken in 1969 in lectures at Stuttgart University (see also Haken & Graham, 1971). It originated from laser physics, where a pronounced transition from the disordered light of a lamp to the highly ordered light of a laser takes place. This transition can be interpreted as a nonequilibrium phase transition, on the one hand (Graham & Haken, 1968, 1970), and as a typical event of self-organization, on the other. Synergetics shows common features with and differences from a variety of interdisciplinary research fields:

1. In common with cybernetics as introduced by Norbert Wiener (1948), synergetics looks for general laws common to physical and biological systems. While cybernetics focuses on the control of a system in order to achieve its specific performance, synergetics studies the various dynamical structures a complex system can acquire.

2. Synergetics shares with general system theory as introduced by Ludwig von Bertalanffy (1968) the aim of finding general laws, in particular by seeking analogies. But while von Bertalanffy was seeking such analogies between otherwise different systems at the level of their individual elements, synergetics establishes close analogies at the level of order parameters (macroscopic field variables; see below).

3. Synergetics has used and developed methods belonging to dynamical systems theory (see, e.g., Guckenheimer & Holmes, 1983; Haken, 1983). Here in particular, emphasis is laid on the qualitative changes of the behavior of dynamical systems close to their points of instability (singular points, bifurcation points). In contrast to, for example, bifurcation theory, synergetics takes into account the pivotal role of random processes (Haken, 1983).

4. Synergetics has used and developed methods from statistical physics, such as various types of (generalized) Fokker–Planck equations, Langevin equations, and master equations (see, e.g., Stratonovich, 1963, 1967).

5. Synergetics shares with the theory of dissipative structures as introduced by Ilya Prigogine the goal of

general laws (Nicolis & Prigogine, 1977). But while Prigogine's theory of dissipative structures is mainly based on thermodynamic principles, such as the entropy production principle or excess entropy production principle, synergetics is based on an approach that is close to statistical physics.

6. The concepts of synergetics have similarities with ideas developed in Gestalt theory founded by Max Wertheimer and Wolfgang Köhler (1924, 1969).

Theoretical Approach

All systems are considered subject to fixed internal or external conditions that are described by control parameters α . At particular values of α the behavior of the system may change macroscopically and qualitatively ("instability" of the previous state). As synergetics shows, close to such instability points the behavior of the system is determined by a small number of dynamical quantities, the order parameters. According to the "slaving principle" of synergetics, the order parameters determine the behavior of the individual parts of the system. In turn, the individual parts generate the order parameters by their cooperation (circular causality). Close to the instability points, nonequilibrium phase transitions occur that are characterized by symmetry breaking, critical fluctuations, and critical slowing down of the order parameters. This approach requires knowledge of the microscopic dynamics (*microscopic synergetics*). If this knowledge is absent, in *phenomenological synergetics* an order parameter dynamics is postulated.

Outline of Microscopic Synergetics

The multi-component system is described by its state vector q , whose components are labeled by the subsystem ℓ and the state or component j of each of them, q_{tj} , $\ell = 1, \dots, N$; $j = 1, \dots, J$. In continuous media, q becomes a function of a spatial coordinate x , $q(x)$. The state vector obeys an evolution equation

$$dq(t)/dt = N(q(t), \nabla, x, \alpha) + F(q, x, t). \quad (1)$$

N is a nonlinear vector-valued, nonlinear function of q , ∇ indicates spatial derivatives, α control parameters, and F fluctuating forces. F is mostly assumed to be δ -correlated in time ("white noise").

It is assumed that for a value $\alpha = \alpha_0$, the solution to (1) is known and the stability of α_0 : $q_0(t)$ is studied by *linear stability analysis*, putting $q(t) = q_0(t) + \xi(t)$ and $F = 0$. This leads to

$$d\xi(t)/dt = L(q_0(t), \alpha)\xi, \quad (2)$$

where the linear operator L depends on $q_0(t)$. The solutions to (2) are of the form

$$\xi_k(t) = \exp(\lambda_k t) v_k(t), \quad k = 1, \dots \quad (3)$$

If λ_k has a discrete spectrum, then (Haken, 1983):

(a) q_0 is time-independent (fixed point); v_k is time-independent and contains powers of t if λ_k is degenerate;

(b) q_0 is time-periodic (limit cycle); v_k is time-periodic with the same period and contains powers of t if λ_k is degenerate and

(c) $q_0(t)$ is on torus, or arbitrary; $|v_k(t)|$ increases in time more slowly than exponential.

Close to instability points, where $\text{Re}\lambda_k \geq 0$ for some k , we distinguish between unstable modes, v_u , and stable modes, v_s . In the case of (a), the wanted solution is assumed in the form

$$q(t) = q_0 + \sum_u \xi_u(t) v_u + \sum_s \xi_s(t) v_s, \quad (4)$$

where the amplitudes ξ_u and ξ_s are still to be determined by inserting (4) into the complete Equations (1) and projecting onto the modes v_k . This yields the equations

$$d\xi_u/dt = \Lambda_u \xi_u + \tilde{N}_u(\xi_u, \xi_s) + F_u, \quad (5)$$

$$d\xi_s/dt = \Lambda_s \xi_s + \tilde{N}_s(\xi_u, \xi_s) + F_s. \quad (6)$$

In the cases, (b) and (c), the hypothesis (4) must be extended to include phase angles, ϕ . In such a case, Equations (5) and (6) must be supplemented by equations for ϕ

$$d\phi/dt = \hat{N}_\phi(\xi_u, \xi_s, \phi) + F_\phi, \quad (7)$$

where $\hat{N}_\phi$ is 2π -periodic in ϕ . In this case, the nonlinear functions on the right-hand side of (5) and (6) become also ϕ -dependent with periodicity 2π . The slaving principle of synergetics allows us to express the enslaved amplitudes ξ_s by means of the order parameters ξ_u, ϕ at the same time

$$\xi_s(t) = \mathbf{f}(\xi_u(t), \phi(t), t). \quad (8)$$

The explicit time dependence stems from the action of the fluctuating forces F . By means of (8), the originally high-dimensional system (5)–(7) can be reduced to a low-dimensional system

$$d\tilde{\xi}_u/dt = \tilde{N}(\tilde{\xi}_u) + \tilde{F}_u, \quad (9)$$

where $\tilde{\xi}_u$ comprises both ξ_u, ϕ . In continuous media, where

$$\xi_u(t) \rightarrow \xi_u(\mathbf{x}, t), \quad (10)$$

the order parameter equations (9) are replaced by generalized Ginzburg–Landau equations

$$d\xi_u(\mathbf{x}, t)/dt = \Lambda_u(\nabla)\xi_u(\mathbf{x}, t) + \tilde{N}(\xi_u(\mathbf{x}, t)) + F_u, \quad (11)$$

where the matrix of eigenvalues Λ_u depends on differential operators. In higher approximation, $\tilde{N}$ also depends on differential operators, $\tilde{N}(\xi_u, \nabla)$.

While Equations (1), (9), and (11) are of Langevin type, the stochastic problems can also be formulated by means of the Fokker–Planck equation, where the distribution function depends on the vector $[\xi, f(\xi, t)]$ and f obeys the Fokker–Planck equation

$$\begin{aligned} \partial f / \partial t &= Lf, \\ L &= - \sum_j \frac{\partial}{\partial \xi_j} (\tilde{N}_j f) \\ &\quad + \sum_{ij} Q_{ij} \partial^2 / \partial \xi_i \partial \xi_j f. \end{aligned} \quad (12)$$

Furthermore, another approach is based on the master equation for the distribution function P obeying

$$\begin{aligned} dP(\mathbf{m}, t)/dt &= \sum_{m'} w(\mathbf{m}, \mathbf{m}') P(\mathbf{m}', t) \\ &\quad - P(\mathbf{m}, t) \sum_{m'} w(\mathbf{m}', \mathbf{m}), \end{aligned} \quad (13)$$

where $w(\mathbf{m}, \mathbf{m}')$ are the transition probabilities from state $\mathbf{m}' \rightarrow \mathbf{m}$.

Phenomenological Synergetics

In the case where microscopic dynamics of the system are not known, the analysis is based on phenomenological equations of the type (9), where the order parameters are characterized by those experimentally determined macroscopic quantities that change qualitatively when the control parameters are changed.

Applications of Concepts and Methods of Synergetics

Physics and Chemistry

Synergetics approaches are used to study stochastic properties and spatiotemporal patterns of laser light and of fluids and plasmas, current distributions in semiconductors, crystal growth, and meteorological structures, for example, baroclinic instability.

Synergetics is also used to study the formation of spatiotemporal patterns at macroscopic scales in chemical reactions, for example the Belousov–Zhabotinsky reaction.

Biology

Based on Turing's ideas of morphogenesis, synergetics calculates spatial density distributions, in particular gradients, stripes, hexagons, etc., in dependence on boundary and initial conditions. In initially undifferentiated omnipotent cells, molecules are produced as activators or inhibitors that diffuse between cells and react with each other and thus can be transformed. At places of high concentration, the activator molecules switch on genes that, eventually, lead to cell differentiation.

By means of synergetics, new kinds of analogies between evolution in biological and physical systems

have been unearthed. For instance, the equations established by Manfred Eigen (1971) for prebiotic, that is, molecular evolution, turn out to be isomorphic to specific rate equations for laser light (photons), where a specific kind of photon wins the competition between different kinds.

In population dynamics, the resources, such as food, nesting places for birds, or light intensity for plants, serve as control parameters for synergetic analyses of self-organization. The numbers or densities of the individuals of species serve as order parameters. Specific examples are provided by the Verhulst equation or the predator-prey relation of the Lotka-Volterra equations. Of particular interest are dramatic changes, for instance the dying out of species under specific control parameter values. This has influences on environmental policy. If specific control parameters exceed critical values, the system's behavior can change dramatically. For instance, beyond a specific degree of evolution, the fish population of a lake may die out.

Nearly all biological systems show more or less regular rhythms—periodic oscillations or fluctuations. These can be imposed on the system from the outside, for instance, by the day/night cycle or seasons (exogen), or produced by the system itself (endogen). Endogenous rhythms that may proceed on quite different spatial and temporal scales are widely researched in synergetics. Examples are cell metabolism, circadian rhythms, brain waves in different frequency bands (see below), menstrual cycles, and cardiovascular rhythms. For instance, in the last, Stefanovska et al. (2000) were able to identify five order parameters. For certain time intervals, these order parameters can show phase and frequency couplings.

Rhythmical movements of humans and animals show well-defined patterns of coordination of the limbs, for instance, walking or running in humans or gaits of quadrupeds. Synergetics studies especially transitions between movement patterns, for instance the paradigmatic experiment by Kelso (1995). If subjects move their index fingers in parallel at a low frequency; increasing the frequency results in an abrupt involuntary transition to a new symmetric movement. The control parameter is the prescribed finger movement frequency, the order parameter is the relative phase between the index fingers. The experimentally proven properties of a nonequilibrium phase transition (critical fluctuations, critical slowing down, hysteresis) substantiate the concept of self-organization and exclude that of a fixed motor program. Numerous further coordination experiments between different limbs can be represented by the Haken-Kelso-Bunz model (Haken et al., 1985). Gaits of quadrupeds and transitions between them have been modeled in detail (Schöner et al., 1990).

In visual perception, the recognition of patterns, for example, faces, is interpreted as the action of

an associative memory in accordance with usual approaches. Here incomplete data (features) with which the system is provided from the outside are complemented by means of data stored in the memory. A particular aspect of the synergetic approach is the idea that pattern recognition can be conceived as pattern formation. This is not only meant as a metaphor, but means also that specific activity patterns in the brain are established. In pattern formation, a partly ordered pattern is provided to the system whereby several order parameters are evoked that compete with each other dynamically. The control parameters are so-called attention parameters that in cases without bias are assumed to be equal. The winning order parameter imposes a total pattern on the system according to the slaving principle. This process is the basis of the synergetic computer for pattern recognition (Haken, 1991). By means of appropriate preprocessing an invariance of the recognition process against scales, displacements and rotations, and even deformations can be achieved.

Gestalt Psychology

As is shown in Gestalt psychology (Wertheimer, Köhler), *Gestalt* is conceived as a specific organized entity to which in synergetics an order parameter with its synergetic properties (slaving principle) can be attached. The cognition or perception process of Gestalt proceeds in principle according to the synergetic process of pattern recognition. The winning order parameter generates, according to the slaving principle, an ideal percept that is the corresponding Gestalt. In ambiguous patterns, an order parameter is attached to each percept of an object. Because in ambiguous figures two or more possible interpretations are contained, several order parameters participate in the dynamics whereby the attention parameters become dynamical quantities. As already assumed by Köhler and as is shown by the synergetic equations, the corresponding attention parameter saturates; that is, it becomes zero if the corresponding object has been recognized and the other interpretation now becomes possible, where again the corresponding saturation process starts, etc. The model equations allow us also to take into account bias. (See the article on **Gestalt phenomena**.)

Psychology

According to the concept of synergetics, psychological behavioral patterns are generated by self-organization of neuronal activities under specific control parameter conditions and are represented by order parameters. In important special cases, the order parameter dynamic can be represented as the overdamped motion of a ball in mountainous terrain. By means of changes in the control parameters, this landscape is deformed and allows new equilibrium positions (stable behavioral patterns). This leads to new approaches to

psychotherapy: destabilization of unwanted behavioral patterns by means, for example, of new external conditions or new cognitive influences and measures that support the self-organization of desired behavioral patterns. The insights of synergetics have been applied in the new field of psychosynergetics with essential contributions by Schiepek, Tschacher, Hansch, and others (Tschacher et al., 1992; Hansch, 1997; Ciompi, 1998, 1999).

Brain Theory

According to a proposal by Haken (1983), the brain of humans and animals is conceived as a synergetic, that is, a self-organizing system. This concept is supported by experiments and models on movement coordination, visual perception, and Gestalt psychology and by EEG and MEG analysis (see below). The human brain with its 10^{11} neurons (and glia cells) is a highly interconnected system with numerous feedback loops. In order to treat it as a synergetic system, control parameters and order parameters must be identified. While in synergetic systems of physics, chemistry, and partly biology the control parameters are fixed from the outside, for instance, by the experimenter, in the brain and in other biological systems, the control parameters can be fixed by the system itself. In modeling them it is assumed, however, that they are practically time-independent during the self-organization process. Such control parameters can be, among others, the synaptic strengths between neurons that can be changed by learning according to Hebb (1949), neurotransmitters, such as Dopamin, Serotonin, and drugs that block the corresponding receptors (e.g., Haloperidol, Coffein), and hormones (influencing the attention parameters). Furthermore, the control parameters may be more or less permanent external or internal stimuli.

In the frame of the given control parameters, self-organization takes place in neuronal activity whereby the activity patterns are connected with the corresponding order parameters by means of circular causality. The order parameters move for a short time in an attractor landscape whereby the attractor and also the order parameter disappear (concept of quasi-attractors). An example is the disappearance of a percept in watching ambiguous figures. The origin and disappearance of quasi-attractors and the corresponding order parameters can happen on quite different time scales, so that some of them can act as attractors practically all the time or are hard to be removed (psychotherapy in the case of behavioral disturbances). The activity patterns can be stimulated by external stimuli (exogenous activity) but can also be created spontaneously (endogenous activity), for instance in dreams, hallucinations, and, of course, thinking.

Synergetics throws a new light on the mind-body problem, for instance the percepts are conceived as

order parameters, whereas the parts of a system are represented by electrochemical activities of the individual neurons. Because of circular causality, the percepts as order parameters and the neural activity (the "enslaved parts") condition each other. Beyond that, the behavior of a system can be described at the level of order parameters (information compression) or at the level of the activities of individual parts (large amount of information).

Analysis of Electroencephalograms (EEG) and Magnetoencephalograms (MEG)

Neuronal activity is accompanied by electromagnetic brain waves that cover the brain over large areas. The corresponding electric and magnetic fields are measured by the EEG and MEG, respectively. According to the ideas of synergetics, at least in situations where the macroscopic behavior changes qualitatively, the activity patterns should be connected with few order parameters. Typical experiments are the above-described finger coordination experiments by Kelso and closely related experiments, for instance, the coordination between the movement of a finger and a sequence of acoustic signals. In a typical experiment, parts of the brain or the whole brain are measured by an array of SQUIDS (superconducting quantum interference devices) that allows the determination of spatiotemporal field patterns. By means of appropriate procedures, these patterns are decomposed into fundamental patterns. As the analysis shows, two dominant basic patterns appear, whose amplitudes are the order parameters. If the coordination between finger movement and the acoustic signal changes dramatically, the dynamics of the order parameters also does so.

Sociology

Here we may distinguish between the more psychological and the more systems theoretical schools, where synergetics belongs to the second approach. We can distinguish between a qualitative and a quantitative synergetics (for a quantitative approach, see Weidlich, 2000). In the latter case, a number of sociologically relevant order parameters are identified. One example is the language of a nation. After his/her birth, a baby is exposed to the corresponding language and learns it (in technical terms of synergetics: the baby is enslaved) and then carries on this language as an adult (circular causality). These language order parameters may compete, where one wins (e.g., in the United States, the English language), they may coexist (e.g., in Switzerland), or they may cooperate (for instance, popular language and technical language). Whereas in this case the action of the slaving principle is evident, in the following examples its applicability is critically discussed by sociologists so that instead of slaving, some sociologists like to speak of binding or consensualization. Corresponding

order parameters are type of state (e.g., democracy, dictatorship), public law, rituals, corporate identity, social climate in a company, and ethics. The latter example is particularly interesting, because order parameters are not prescribed from the outside or *ab initio*, but originate through self-organization and need not be uniquely determined.

Ethics

Conceived as order parameter means that it originates from the formation of a consensus so that the slaving principle becomes valid and also that there may exist several ethics.

Epistemology

An example for order parameters is provided by the scientific paradigms in the sense of Thomas S. Kuhn (1970), where a change of paradigms has the properties of a nonequilibrium phase transition, such as critical fluctuations and critical slowing down. Synergetics as a new scientific paradigm is evidently self-referential. It explains its own origin.

Management

The concept of self-organization is increasingly used in management theory and management praxis. Instead of fixed order structures with many hierarchical levels, now flat organizational structures with new hierarchical levels are introduced. In the latter case, a hierarchical level makes its decisions by means of its distributed intelligence. For an indirect steering of these levels by means of a higher level, specific control parameters in the sense of synergetics must be fixed, for instance, by fixing special conditions and goals. The order parameters are, for instance, the self-organized collective labor processes. In this context, the slaving principle—according to which the order parameters change slowly, whereas the enslaved parts react quickly (adaptability)—gains a new interpretation. For instance, the employees that are employed for a longer time determine the climate of labor and the style of work whereby it can also be possible that undesired cliques are established. This trend can be counteracted by job rotation.

Development of Cities

So far the development of cities was based on the concept of city planning with detailed plans for areas, but new approaches use concepts of self-organization according to synergetic principles. Instead of a detailed plan, now specific control parameters, such as a general infrastructure (streets, communication centers, and so on), are fixed. For details consider the book by Portugali (1999).

T

TACHYONS AND SUPERLUMINAL MOTION

With a name derived from the Greek *tachys* (for swift), the tachyon is a hypothetical elementary particle that travels at speeds exceeding that of light (superluminal speed). In his 1905 paper on special relativity, Albert Einstein showed that the light speed in vacuum (c) is invariant with respect to all inertial observers, constituting a limiting value for the speed (v) of a moving mass. Consequently, tachyon research was delayed until the 1950s and 1960s, in particular till the appearance of the papers by Sudarshan and coworkers (Bilaniuk et al., 1962), and later by Recami and coworkers, among others.

If the special relativity theory is not a priori restricted to subluminal speeds, however, it seems able to accommodate tachyons. Such an extended relativity (ER) is based on the ordinary postulates of special relativity, and, therefore, does not appear to imply violations of causality (Recami, 1986). Just as photons are born, live, and die, always at the speed of light (without any need of accelerating from rest to the light speed), particles or waves may exist endowed always with speeds v larger than c .

Several areas of experimental physics suggest superluminal group velocities and energy propagation although it is not yet clear whether these phenomena imply signal and information transmissions with faster-than-light speeds (Recami, 2001).

Evanescence Waves and Tunneling Photons

In quantum mechanics, the tunneling time does not depend on the potential barrier width, implying arbitrarily large group velocities inside long barriers (Olkhovsky et al., 1992). Analogously, evanescent electromagnetic waves that travel with superluminal speeds have been predicted by extended relativity, confirmed by computer simulations based on Maxwell equations, and empirically observed (Chiao et al., 1993).

The most interesting experiment of this series was performed in 1994 by Günter Nimtz and his colleagues using two classical barriers separated by

an intermediate region of width R . For nonresonant tunneling of microwaves, it was claimed that the total crossing time did not depend on R , implying the speed of transmission to be therein practically infinite. This result agrees with theoretical predictions for nonresonant tunneling through two successive opaque barriers (Olkhovsky et al., 2002) that were experimentally confirmed and have been verified by an experiment with two gratings in an optical fiber, suggesting potentially important applications.

Superluminal Localized Solutions (SLS) to the Wave Equation

Although the simplest subluminal object is a small sphere (or a point), a result of ER is that the simplest superluminal objects appear as “X-shaped” waves (double cones), rigidly moving in a homogeneous medium. Beams of this sort have been constructed (as superpositions of Bessel beams) in experiments with acoustic waves (Lu and Greenleaf, 1992), electromagnetic waves, and visible light (Saari & Reivelt, 1997). A single Bessel beam is the following solution of the

Figure 1. Illustration of the real part of a classical X-shaped wave (as a function of $\xi \equiv z - vt$ and the radial coordinate ρ), evaluated for $v = 5c$ and $a = 5 \times 10^{-7}$ m, plotted from Equation (3).

Figure 2. A spring–mass system with nonlinear springs. (Upper) Masses at rest. (Lower) A supersonic compression wave.

Maxwell equations in vacuum:

$$\psi(\rho, \zeta) = J_0[\omega\rho/c \sin \theta] \exp[i\omega\zeta/c \cos \theta], \quad (1)$$

where J_0 is a Bessel function of the first kind of order zero, $\zeta \equiv z - vt$, $v = c/\cos \theta$, and θ is the axicone angle (angle between the direction of propagation and the propagating cone). This solution depends on z and t only through the quantity ζ ; thus, it propagates without dispersion along the z -axis with speed $v > c$. By superposition of Bessel beams, for example, with variable angular frequency ω but constant θ and, therefore, constant v , one can obtain additional solutions to the Maxwell equations with any degree of transverse and longitudinal localization and centered at the desired angular frequency ω with the desired bandwidth (Zamboni-Rached et al., 2002); thus

$$\Psi(\rho, \zeta) = \int_0^\infty S(\omega) J_0[\omega\rho/c \sin \theta] \times \exp[i\omega\zeta/c \cos \theta] d\omega. \quad (2)$$

By choosing the exponential spectrum $S(\omega) = \exp[-a\omega]$, one gets the ordinary X-wave (with $v \equiv c/\cos \theta > c$)

$$\Psi(\rho, \zeta) = v \left[\sqrt{(av - i\zeta)^2 + \rho^2(v^2/c^2 - 1)} \right]^{-1}, \quad (3)$$

which is a superluminal localized solution (SLS) to the wave equation. The plot of Equation (3) in Figure 1 can be understood as follows. For $\zeta < 0$, one has the familiar bow wave of a moving boat or shock wave of a supersonic aircraft. The branches for $\zeta > 0$, on the other hand, prepare the medium for the superluminal disturbance.

SLSs have also been constructed which travel without distortion along cylindrical waveguides and coaxial cables (Zamboni et al., 2002). X-shaped waves keep their localization and superluminality properties only to a certain depth of field (whose length can be determined a priori), decaying abruptly thereafter. As

suggested by extended relativity, the simplest means for experimentally producing SLSs employs dynamic antennas consisting of a set of circular rings (or axicons or holographic elements). Acoustic localized supersonic beams have been used in a 3-dimensional ultrasound scanner for medical purposes: high-resolution scanning of the heart (Lu & Greenleaf, 1992).

Tachyons and SLSs in Nonlinear Media

Localized solutions for nonlinear partial differential equations that travel faster than the limiting speed for small amplitude waves are not uncommon (Conti et al., 2003). The sine-Gordon equation, for example, is Lorentz invariant and has tachyonic soliton solutions (Scott, 2003). Although dynamically unstable over long distances, these solutions may influence dynamics over shorter spans.

Another well-known example of a SLS goes back to the birth of nonlinear science, when John Scott Russell measured the speed of a hydrodynamic solitary wave in a wave tank to be $\sqrt{g(d+h)}$, where g is the acceleration of gravity, d the depth of the channel, and h the wave height. Clearly, the solitary wave speed is larger than the speed $\sqrt{gd}$ of low-amplitude waves.

Similar phenomena are observed for lattice solitary waves on spring-mass ladders (see Figure 2), which include the Fermi–Pasta–Ulam system, the Toda lattice, and various generalizations: Existence of supersonic compression-wave solutions has been mathematically proven for a general class of nonlinear intermass potentials (Friesicke & Wattis, 1994). As an example of superluminal propagation that was well known to military engineers in the early 19th century, Russell cited the fact that “the sound of a cannon travels faster than the command to fire it”.

TACOMA NARROWS BRIDGE COLLAPSE

The Tacoma Narrows suspension bridge in Washington state was opened to traffic on July 1, 1940. At the time, it was the latest in a trend in suspension bridge design toward building ever longer, lighter, and more flexible bridges. At least two other suspension bridges in America, the Golden Gate bridge in San Francisco and the Bronx–Whitestone bridge in New York, had at that time, already experienced some problems with unwanted oscillations; these bridges were stabilized by adding dampers, stiffening girders, and additional cables. The Tacoma Narrows bridge was far lighter and more flexible than its predecessors.

From its opening, the bridge experienced relatively small vertical oscillations. These were observed, and carefully recorded and the record survives in Amann et al. (1941), which is our primary source for what follows.

These oscillations were purely vertical, with no torsional component. They could be anything from no-noded (with a comparatively low frequency of about 8 cycles/min) to as many as seven-noded (with a frequency of 30 cycles/min). Amplitudes were as much as 5 f from top to bottom. Motions as large as 4 f with a frequency of 16 min^{-1} were observed

Figure 1. The Tacoma Narrows Bridge twisting, November 7, 1940. (Courtesy, Manuscripts, Special Collections, University Archives, University of Washington Libraries, UW2143.)

in winds of 3 mi/h, while at other times, the bridge remained stationary in winds of 35 mi/h. The structure had already survived winds of 48 mi/h.

These motions were not considered grounds for alarm, and it was apparently expected that with some modifications, they would eventually be eliminated. By October, hold-down cables had been installed in the side-spans, and these had effectively stopped the oscillations in these spans although, of course, they did not effect the center span. Hold-down cables for the center span had already been ordered.

On the morning of November 7, 1940, a qualitatively different phenomenon occurred. The wind was about 42 mi/h. The bridge began oscillating with somewhat more violence than usual in the vertical direction. The motion appears to have been eight- or nine-noded, with an amplitude of 4–5 f and a frequency of about 36–38 cycles/min. Although this seems rather violent, it was not initially viewed as cause for alarm. People and cars were on the bridge.

Suddenly, without warning, and virtually instantaneously, the bridge switched from the vertical motion to the famous torsional motion most often associated with the bridge (see Figure 1).

This new motion was one-noded, with an angle of rotation of nearly 45° each way, and a frequency of about 14/min. The sides of the bridge were moving with a double amplitude of 28 f, with accelerations in excess of gravity. Amazingly, this motion continued for about 45 min, after which the bridge finally began to break up. Occasionally, it would switch from one-noded to no-noded and back, but it remained primarily one-noded. The side-spans remained motionless, until the collapse of the center span, after which a torsional oscillation built up and then died down.

Thus, we are presented with at least three distinct nonlinear phenomena.

- (i) The vertical oscillations: why so many and under such widely different wind conditions?
- (ii) The instantaneous transition from vertical to torsional motion.
- (iii) The persistence of large torsional periodic oscillation for 45 min under comparatively small aerodynamic forcing.
- (iv) The peculiar shifting from one-noded torsional motion to no-noded and back.

A commission, including Othmar Amann and Theodore von Karman, tried to investigate the cause of the collapse. They made some preliminary conclusions, including "it is very improbable that resonance with alternating vortices plays an important role in the oscillations of suspension bridges." However, the main recommendation was simply to avoid designs that were light and flexible. This advice has largely been followed since that time, with the notable exception of the Millennium Bridge over the Thames in London. Moreover, other light, flexible, long-span bridges such as the Golden Gate were substantially re-engineered at great cost in the 1950s to eliminate similar unwanted oscillations.

Recent advances in nonlinear science have cast light on some of the phenomena mentioned above. The vertical oscillations may have been the result of the existence of multiple periodic solutions of a nonlinearly supported beam equation (Lazer & McKenna, 1990). They may also have been the result of some sort of negative damping induced by the aerodynamic interaction of the wind and the structure. Wind tunnel experiments on scale models (Scanlan & Tomko, 1971), predict the existence of small torsional oscillations (e.g., in torsion $0 \leq \alpha \leq \pm 3^\circ$). However, this type of motion was never observed on the Tacoma Narrows.

The violent transition from vertical to torsional motion is now well understood. In McKenna (1999), a two-degree-of-freedom oscillator with physical constants chosen to match the bridge exhibits exactly this type of instability, as soon as the cables start alternately slackening. Also in McKenna (1999), this oscillator shows how small torsional forcing can induce large torsional periodic solutions, once one takes into account the pendulum-like nonlinearity of the torsional oscillator. The solutions are remarkably similar, in terms of amplitude and frequency, to the behavior observed on the Tacoma Narrows.

The transition from one-noded to no-noded and back has been observed in Moore (2002), where the torsional oscillations in a nonlinear beam are shown to obey a sine-Gordon equation whose long-term solutions are investigated. One can also see a numerical simulation of the bridge at www.math.lsa.umich.edu/ksmoore.

A good source of interesting behavior of early suspension bridges is Bleich et al. (1950).

TAYLOR-COUPETTE FLOW

Taylor-Couette flow is generated in the gap between a pair of concentric cylinders by the rotary motion of one or both of the cylinders. If the outer cylinder alone is rotated, the torque induced by viscous drag on the inner one can be used to measure the viscosity of the fluid in the gap. This technique (studied by Arnulph Mallock in 1888 and independently by M.M. Couette in 1890) is still in use today as the basis of some commercial viscometers.

In 1916, Lord Rayleigh (John William Strutt) proposed general arguments on the stability of rotating fluids, showing that when the centrifugal force gradient decreases outwards in a rotating body of fluid, this will be an unstable situation for an inviscid fluid. In the case of Mallock's viscometer, the flow will be stable. But suppose the inner cylinder is rotated and the outer is held fixed. Here the flow will be unstable according to Rayleigh's criterion, and this question intrigued Geoffrey Taylor. In 1923, he published a brilliant theoretical and experimental investigation of a viscous version of the Rayleigh criterion, using rotating cylinders to generate what has come to be called Taylor-Couette flow. Taylor's work forms the cornerstone of much modern research on hydrodynamic stability

Figure 1. (a) Front view of steady Taylor–Couette cells (G. Pfister). (b) Front view of turbulent spiral flow (O. Dauchot).

and contains important ideas such as the exchange of stability between states.

In the simplest case, the outer cylinder is stationary and the inner cylinder alone rotates. When a critical Reynolds number is exceeded, the initially featureless rotary Couette flow has secondary vortices superposed on it. An example of such a Taylor vortex state is shown in Figure 1(a) where a front view of a Taylor vortex state is shown. The pattern is repeated along the length of the cylinder and has the appearance of a set of doughnuts stacked along the length the inner cylinder.

Increasing the speed of the inner cylinder leads to an instability (Davey et al., 1968) in the form of traveling waves that move at a fixed fraction of the speed of the inner cylinder (Coles, 1965). Yet, further increases in rotation rate give rise to more complicated quasi-periodic motion until low-dimensional temporal chaos ensues within each Taylor cell (Gollub & Swinney, 1975). Nowadays, it is recognized that many routes to chaos exist within this flow (Tagg, 1994), which has proved to be a rich research field for dynamical systems and bifurcation theory.

Taylor considered the general case with both cylinders rotating in co- and counter-directions, obtaining remarkable agreement between theory and experi-

ment for the stability boundary. When the cylinders are rotated in opposite directions, new states of spiraling turbulence are sometimes found (Coles, 1965). An example of such a flow from a more recent study (Prigent et al., 2002) is shown in Figure 1(b). The general case of co- and counter-rotation produces a plethora of interesting dynamical states (Andereck et al., 1986) that can now be classified in terms of equivariant bifurcation theory (Tagg, 1994).

Coles also demonstrated dynamical non-uniqueness when the outer cylinder is stationary, finding more than 20 states at a particular Reynolds number. This multiplicity of solutions has also been observed in the steady vortex states (Burkhalter & Koschmieder, 1973; Benjamin & Mullin, 1982) where evidence was found for 42 different solutions at a single point in parameter space in the latter study.

Most of the above work is based on the notion of a theoretical model where the cylinders are considered to be infinitely long. This permits the use of periodic boundary conditions which allows analytical and numerical progress to be made in the nonlinear regime. However, the importance of end effects and their influence on global aspects of the steady flows was first recognized by Benjamin in 1978. He showed their importance in the selection process for steady flows and discovered the so called “anomalous modes” where all cells rotate in the opposite direction. These modes form an essential part of the solution set. The ideas have been developed and the role of end effects in determining the dynamics is now understood in some detail (Abshagen et al., 2001).

One clear advantage of studying fluid dynamical systems such as Taylor–Couette flow is that quantitative comparisons can be made between the results of controlled laboratory experiments and numerical calculations of the governing equations of motion—the Navier–Stokes equations (Cliffe et al., 2000). This is so not only for steady flows but also for time-dependent states, although disordered motion remains an outstanding challenge.

TENSORS

Tensors are mathematical representations of objects that have intrinsic, geometric significances. This is a rather wider definition than many which can be found in textbooks, often referring to “sets of quantities” that “transform according to hideous formulae.” The best way to understanding is likely to follow a few examples.

Readers interested in learning more will find the books of Simmon (1994) and Dodson & Poston (1991) helpful, as well as that of Bishop & Goldberg (1968). The main caveat, at the risk of repetition, is to beware of books that define tensors as some set of quantities tied to a coordinate system and then describe how they transform—tensors are there whether or not you have coordinates.

Suppose you have some apples on a table. The quantity of apples present is described completely by one number, and that number is well defined and meaningful no matter how you might orient any coordinate axes in the room. The fact that it is meaningful independent of the coordinates makes it a tensor, and the fact that it is the same no matter what coordinates might be introduced makes it a *scalar* or zeroth-rank tensor—the simplest kind of tensor.

Now, consider the weight of one of the apples. This weight is a force, equal to the mass of the apple, m , times the gravitational acceleration ($g = 9.8 \text{ m/s}^2$), and it is directed downwards. That is, its weight is mg directed downwards towards the table top. Let us call this weight $\mathbf{W}$, which has a clear physical meaning independent of coordinates, although it is helpful to describe its direction as “downwards.” The fact that $\mathbf{W}$ is well defined even in the absence of coordinates makes it a tensor, and because it has a direction, it is called a *vector*, or first-

rank tensor. If I introduce a set of coordinates x , y , z , I may place these axes in any way I choose. If I put the z -axis pointing downwards, the vector will have components relative to that coordinate system, with only the z component nonzero, and I might describe it as “the vector $(0, 0, mg)$.” This (old) point of view is legitimate but carries with it the need to understand that the *components* are referred to as a coordinate system and as such have no intrinsic meaning.

More complicated objects can be easily imagined. For example, there could be a wind blowing across the table, and that could be described by another vector $\mathbf{V}$ describing its velocity. Referred to a coordinate system, it would be described by three components, and the presence of these two vectors is clearly something of intrinsic geometric significance. We can think of a product of the two vectors, meaning simply all the information needed to describe them. In terms of coordinates, if the weight is described by components w_i with i ranging from 1 to 3 and the wind velocity by v_j with j ranging from 1 to 3, we can think of a single geometric object $\mathbf{V} \otimes \mathbf{W}$ called the *tensor product* of $\mathbf{V}$ and $\mathbf{W}$ with 9 components $(\mathbf{V} \otimes \mathbf{W})^{ij} = v^i w^j$. The object $(\mathbf{V} \otimes \mathbf{W})$ is called a second-rank tensor, and this construction can be repeated to create more and more complex objects. (The reason for the upper placement of indices will be made clear shortly.)

The example given above was chosen to make it clear that tensors can turn up anytime one has vectors, but it is easy to find more physically motivated examples. Suppose one has a perfect fluid of density ρ moving with velocity $\mathbf{V}$ with components v^i . Density is a scalar if we allow only “proper” rotations which cannot change the signs of volumes. The flux or mass per unit volume per unit area perpendicular to direction i flows has components ρv^i . The flux of momentum in direction j is $\rho v^i v^j$. This motivates defining the second-rank “momentum tensor” $\mathbf{T} = \rho \mathbf{V} \otimes \mathbf{V}$ with components $T^{ij} = \rho v^i v^j$.

All the tensors of a given rank have the structure of a vector space which they inherit from the operations allowed on vectors: they can be added, or multiplied by scalars. In fact, all the machinery of linear algebra carries over directly to them.

There has been an implicit indication that tensors here have something to do with symmetry or a concept of allowed transformation of the coordinates. The class of acceptable coordinate systems defines the geometry in any given situation, and we can speak then of tensors with respect to a symmetry group. For example, if we allow arbitrary rotations of a given orthogonal coordinate system, we can speak of “Cartesian tensors” or tensors under the group of orthogonal transformations in three dimensions. This means that one can pass from a representation of a tensor in terms of components with respect to one coordinate system to another by making the coordinates

transform according to a matrix which represents that coordinate change.

This final step in thinking clarifies the notion of what a tensor must be. Given some space, one considers the geometry to be defined by the group of transformations which leave it invariant. For example, in flat Euclidean three-dimensional space, one might take the group of rotations, which are orthogonal matrices of determinant one, or $SO(3)$. The vectors and tensors we have been talking about so far are then elements of spaces in which $SO(3)$ acts linearly, i.e., they lie in representation spaces of $SO(3)$.

Depending on the space in question and the structures imposed upon it, special tensors and operations can be defined. For example, in three-dimensional flat space, we have an operation that takes two vectors and produces from them a (coordinate-independent!) scalar called the “dot product,” “inner product,” or “scalar product.” This is defined using the Kronecker delta δ_{ij} which is defined to have the value 1 when $i = j$ and 0 otherwise. It is a geometric object with a well-defined meaning independent of coordinates and is, thus, a tensor but of a different kind. One says that while $v^i w^j$ are components of a “contravariant tensor,” δ_{ij} are the components of a “covariant tensor.” The expression $\sum_i \sum_j \delta_{ij} v^i w^j$ is the scalar product of v and w and is a scalar. The terms *covariant* and *contravariant* are historical and come from the idea that for a quantity such as $\sum_i \sum_j \delta_{ij} v^i w^j$ to be invariant, the components with upper and lower indices should transform differently under a change of coordinates. The summation signs are often omitted, with a summation over repeated indices implied following the so-called “Einstein summation convention.” An inner product automatically provides a dual space to that of the tensors, and one can write $v_i = \delta_{ij} v^j$ and speak of “covariant” as opposed to “contravariant” components of v , and of the use of δ_{ij} to “lower indices.”

The concept of a tensor is independent of any notion of a dot product, but many spaces of interest have such a product naturally present. In special relativity, for example, we consider “four-vectors” labeling differences in space and time and requiring four components. In units where the speed of light is unity, the dot product is provided by the Minkowski metric tensor η_{ab} : (a, b running from 0 to 3) where η_{ab} is 1 when $a = b = 0$, -1 when $a = b \neq 0$, and zero otherwise. This dot product is preserved by a larger group than just rotations, and this group is the Lorentz group of rotations and boosts, also called $SO(3,1)$. Note that it is not positive-definite, so it is not an inner product in the strict sense of the word, and it defines a pseudo-Euclidean metric. In this case, we have $SO(3,1)$ vectors as opposed to $SO(3)$ vectors.

The most general (pseudo-)Riemannian geometry provides a dot product in terms of a metric tensor

g_{ab} which is similar to η_{ab} but unrestricted other than to be nonsingular. In general relativity, we allow all invertible linear transformations in four dimensions, the symmetry group is $GL(4)$, and we have $GL(4)$ tensors for physical quantities.

TESSELLATION

A tessellation (or tiling) is a covering of a surface with tiles so that there are no gaps or overlaps. The tile shapes can be all different, as in the chips used to produce a complex Byzantine mosaic, or they may consist of a limited number of shapes, each congruent to one or more “prototiles” which serve as templates. Since ancient times, almost every culture has produced tessellations for utilitarian or decorative purposes—on walls, ceilings, and roofs of buildings, for pavements and plazas, and for designs to be woven, painted, printed, incised, or inlaid on every variety of surface. Tessellations adorn many churches, temples, palaces, and mosques; perhaps the most celebrated geometric tessellations are found in the Alhambra, in Granada, Spain. Tessellations also occur in nature, in the designs formed by scales or packed cells on a living surface.

Although artisans have produced tessellations for thousands of years, only recently have mathematicians undertaken a methodical study of the subject. Grünbaum and Shephard’s book is the most complete reference. Intuitively, a shape “tiles” (is a prototile for a tessellation) if congruent copies of that shape can be fitted together exactly to fill a surface. Every triangle and every quadrilateral can tile the plane, and convex polygons with seven or more sides can never tile the plane. All convex hexagons that tile the plane have been determined, and 14 classes of convex pentagons that tile have been discovered, but it is not known if there are others. Tessellations by regular polygons appear frequently; those known as Archimedean tessellations are composed of regular polygons with edges matched, and have the same arrangement of tiles occurring at every vertex of the tiling (Figure 1).

An infinite variety of shapes tile the plane, many of them classified by special properties. Given an arbitrary set of shapes, many tests can attempt to answer the question: Will these tile the plane? But there is no guarantee of an answer. The question is mathematically

Figure 1. The 11 Archimedean tessellations. The three with only one prototile are called regular tessellations; the others are often called semiregular.

undecidable; that is, there is no algorithm that can deliver an answer of yes or no for every possible set of shapes.

M.C. Escher, a Dutch graphic artist (1898–1972), is the best-known creator of tessellations using whimsical figures as tiles (Figure 2). Inspired by the geometric tessellations in the Alhambra, he sought to answer the question: What shapes can tile the plane so that every tile is surrounded in the same way? As he discovered some answers, he developed a system of tile types that enabled him to create imaginative shapes that fit together in a prescribed manner. In his lifetime, he produced more than 150 finished tessellations; many have been used by scientists, particularly crystallographers, to illustrate their theories.

Almost all tessellations with repetition (including those in Figures 1 and 2) are periodic, that is, there is a smallest patch of the tiling that can be translated repeatedly by two independent vectors to fill out the whole tiling. It is natural to want repetition in a predictable manner to lay tile, to print, or to weave a pattern. Symmetry groups of periodic tilings are known as two-dimensional crystallographic groups, because crystals, by definition (until very recently), were defined by their periodic molecular structure. These groups consist of the translations, rotations, reflections, and glide-reflections that can act on the tiling in such a way that each tile moves to fit exactly onto another, leaving the tiling invariant. There are only 17 distinct symmetry groups for periodic tilings in the Euclidean plane; these are frequently used to classify tilings. Colored tilings (such as an extended checkerboard or Escher's tilings) can be analyzed according to color symmetries, which permute colors of tiles as well as positions of tiles in the tiling.

Nonperiodic tessellations have no translation symmetry. Although a regular tiling by squares can be made

Figure 2. An Escher tessellation covers a column in a school in Baarn, Holland. (All M.C. Escher works © Cordon Art B.V., Baarn, The Netherlands.)

Figure 3. A Penrose tiling by kites and darts requires matching vertices of the same color.

nonperiodic by shifting a few rows a small distance, the most interesting nonperiodic tessellations are produced by an aperiodic set of prototiles—every tiling formed by such a set is nonperiodic. It is not known if there is a single aperiodic tile, but there are several known aperiodic sets of two or more prototiles. The most well-known pairs were discovered by Roger Penrose in the 1970s: a kite and a dart (or a thick and a thin rhombus). In each Penrose tiling formed by these pairs (Figure 3), every patch of the tiling repeats infinitely often, but never by a translation that leaves the tiling invariant. Some properties of Penrose tilings are similar to those exhibited by unusual alloys discovered in the 1980s. These were named quasicrystals because their X-ray diffraction patterns displayed a crystal-like orderly repetition of bright spots, but also exhibited rotation symmetry forbidden in a periodic structure. Many unusual properties of Penrose and other aperiodic tilings have been discovered, and various techniques have been developed to study their structure (Senechal, 1995). Yet the study of aperiodic tilings and of quasicrystals is in its infancy, and it remains to be seen if the connections between them are more than superficial.

A Voronoi (or Dirichlet) tessellation is determined by a given discrete set S of points in a surface. Each point x of S is surrounded by the region of points that are closer to x than to any others in S . The boundaries of these regions consist of those points that lie equidistant between at least two points of S . These regions with their boundaries (called Voronoi polygons or Dirichlet domains) are the tiles of the Voronoi tessellation determined by S . Such tessellations arise naturally in a wide variety of applications in physics (Wigner–Seitz regions); crystallography (Wirkungsbereich); physiology (capillary domains); urban planning (regions of service for schools or fire stations); biology (modeling cell arrangement); statistical spatial data analysis; and many other areas. Such tilings are almost always nonperiodic with many differently shaped tiles. Mathematical properties of such tilings and various algorithms to construct them are vigorous areas of research (Okabe et al., 1992).

Tessellations on surfaces such as spheres or the hyperbolic plane and tessellations of space of three or higher dimensions are equally important. Which shapes can fill space, and in what manner, is of great interest to scientists (and manufacturers). Little is known in this area; there is not even a complete list of space-filling tetrahedra. Other topics of investigation are tessellations with special tiles (e.g., polyominoes, or fractal tiles), relationships between local and global properties, classification, and construction of tessellations with special properties.

THERMAL CONVECTION

Thermal convection is the transfer of heat by flow. In general, heat can be transported by convection, conduction, or radiation. In all cases, heat transfer requires the presence of a temperature gradient, and heat is transported from high to low temperature. Conduction is a diffusive process that involves the exchange of energy via collisions between molecules in a gas or a liquid, or interactions between lattice waves or electrons in a solid. Heat transport by radiation results from the emission and absorption of electromagnetic waves. Convection, finally, involves the transport of heat by the bulk physical motion of a fluid medium. The flow can arise naturally, due to thermal expansion—hot fluid is less dense than cold fluid and so tends to rise, while cold fluid is more dense and tends to fall—or it can be forced by some externally applied means.

In a layer of fluid heated from below, thermal convection is known as Rayleigh–Bénard convection, which is one of the most important systems for the study of pattern formation. This is because precise, well-controlled experiments are possible and because the equations describing the system (the Navier–Stokes equations coupled with an equation for heat transport and the appropriate boundary conditions) are well known, allowing close contact among experiment, theory, and simulations.

Figure 1(a) shows schematically an experiment for the study of Rayleigh–Bénard convection. The top plate is maintained at a temperature T_1 , while the bottom plate is at a higher temperature $T_b = T_1 + \Delta T$. The separation between the plates is d . For ΔT small, there is no flow and heat transport across the fluid layer is by conduction. Because of thermal expansion, however, the hotter fluid near the bottom plate is less dense than the cooler fluid above it. This is gravitationally unstable, but initiating flow costs energy due to viscous dissipation. As a result, convection does not begin until ΔT is large enough that the energy gained by starting flow offsets the cost due to dissipation. It is convenient to write ΔT in dimensionless form as the Rayleigh number, given by $Ra = g\alpha d^3 \Delta T / \nu \kappa$, where g is the acceleration due to gravity, α is the thermal expansion coefficient of the fluid, ν is the fluid's viscosity, and κ is its thermal diffusivity. The onset of convection occurs when Ra reaches a critical value Ra_c which depends on the nature of the top and bottom boundaries. For rigid, isothermal boundaries, $Ra_c = 1708$. For a rectangular cell with the same boundaries, the flow appears as a pattern of straight convection rolls oriented parallel to the short side of the cell, with a

Figure 1. A schematic illustration of Rayleigh-Bénard convection. A fluid layer is bounded above and below by plates separated by a distance d , with the bottom plate at a temperature higher by ΔT than the top plate. When ΔT is below a critical value, there is no flow (a), but when ΔT is higher than the critical value, convective flow develops in the form of parallel, counter-rotating convection rolls (b).

wavelength equal to $2.016d$. This situation is shown in Figure 1(b).

Heat transport in a convecting fluid is measured by the Nusselt number Nu , defined as $Nu = \lambda_{\text{eff}}/\lambda$, where λ is the thermal conductivity of the fluid and λ_{eff} is the effective thermal conductivity taking into account the heat transported by the flow. The Prandtl number, $Pr = \nu/\kappa$, affects the dynamics of the flow pattern above onset.

The onset of Rayleigh-Bénard convection is an example of a bifurcation from a uniform (no-flow) state to one characterized by a spatial pattern. It can be described by the Ginzburg-Landau equation, which can be derived from the full equations describing the system. For the case of two rigid, isothermal boundaries, the system is up-down symmetric and the bifurcation is a supercritical pitchfork bifurcation. If we define $\varepsilon = (Ra - Ra_c)/Ra_c$, then the bifurcation occurs at $\varepsilon = 0$. The Ginzburg-Landau equation predicts that close to onset, the amplitude of the convective flow field will grow as $\varepsilon^{1/2}$, while the correlation length of the pattern (the length scale over which the amplitude changes) behaves as $\varepsilon^{-1/2}$. These predictions have been confirmed experimentally.

If the up-down symmetry of the system is broken, either by making top and bottom boundaries different or due to a variation in the fluid properties with temperature across the cell (non-Boussinesq effects), then the symmetry of the bifurcation is also broken and convection appears via a subcritical bifurcation. In this case, the convection pattern at onset takes the form of an array of hexagonal cells (see photo of atmospheric hexagonal convection cells on page 3 of color plate section).

Above onset, the straight-roll pattern is stable within a range of wave numbers and Rayleigh numbers. The

Figure 2. Spiral defect chaos visualized in a convection experiment in a pressurized gas. Spiral defect chaos is a time-dependent steady state that appears near onset at low Prandtl number. Here dark regions indicate upflow and light regions indicate downflow. (Image courtesy of S.W. Morris.)

range of stability (known as the “Busse balloon”) is limited by a variety of secondary instabilities which depend on Pr . The original straight-roll pattern becomes unstable to perturbations in phase or amplitude which lead to new flow patterns, which can have different wave numbers, orientations, and symmetries. Certain of these secondary instabilities can make the flow pattern two- or three-dimensional or time dependent.

In larger systems, when the size of the system becomes much greater than the correlation length of the pattern, the convection patterns are more complex than ideal straight rolls. The tendency of the rolls to orient perpendicular to the sidewalls results in patterns with curved rolls and a spatially varying wave number. Even close to onset, defects and localized instabilities can lead to time-dependent patterns. At low Pr , a transition to a complex, spatiotemporally chaotic state known as spiral defect chaos occurs (Figure 2). Interestingly, spiral defect chaos exists in exactly the regime where ideal straight rolls are expected to be stable, and experiments have shown that the two states can coexist. This suggests that there are two stable states in this regime, with different basins of attraction. Spiral defect chaos is obtained for most conditions, while specially chosen initial or boundary conditions are required to obtain ideal straight rolls.

At high Ra , the convective flow becomes turbulent. In this case, most of the temperature drop occurs in boundary layers near the top and bottom plates of the cell. Coherent plumes of hot and cold fluid can form at the lower and upper boundary layers, respectively, and a coherent large scale flow can exist in the convection cell. Simple theories based on the stability of the boundary layers predict that heat flow for turbulent convection should scale as $Nu \sim Ra^{1/3}$, while more sophisticated models give different values of the

exponent. Recent research indicates that the exponent is itself a function of Ra.

There are many variants of Rayleigh-Bénard convection that have been studied in an effort to elucidate particular aspects of nonlinear dynamics. In appropriately chosen binary mixtures, one can obtain traveling-wave convection patterns. Thermal convection in anisotropic materials (e.g., liquid crystals) also leads to complex dynamics. Convection with an imposed mean flow has been used to study the transition from convective to absolute instability. Convection with rotation exhibits spatiotemporally chaotic patterns close to onset.

THERMO-DIFFUSION EFFECTS

In fluid mixtures, a temperature gradient can drive a concentration current or generate a concentration gradient depending on boundary conditions. This thermo-diffusion effect—nowadays referred to as the Soret effect or Ludwig-Soret effect—was first reported by Carl Ludwig in 1856 and by Charles Soret in 1879. They observed an increase (decrease) of salt concentration at the cold (hot) end of a tube filled with salty water (Ludwig, 1856; Soret, 1879). The reciprocal effect that a concentration gradient drives a heat flow or generates a temperature gradient was first reported by Louis Dufour in 1872 for gas mixtures in a porous medium. Theoretically, these and similar effects are most conveniently captured within the Onsager theory of irreversible macroscopic processes, in which generalized thermodynamic forces and resulting fluxes are linearly related to each other (de Groot & Mazur, 1962; Landau & Lifshitz, 1959).

In the last 20 years or so, it has become clear that the linear Soret effect plays a dominant role in the nonlinear behavior of convective pattern formation in binary fluid mixtures (Platten & Legros, 1984; Cross

& Hohenberg, 1993; Lücke et al., 1998). Consider the typical Bénard configuration of a horizontal fluid layer of height d that is heated from below in a homogeneous gravitational field, $\mathbf{g} = -g \mathbf{e}_z$. Strongly heat-conducting impermeable horizontal plates impose a vertical temperature difference ($\Delta T > 0$) such that $T = T_0 \pm \Delta T/2$ at $z = \mp d/2$. T_0 is the mean temperature of the fluid layer. At small ΔT , the laterally homogeneous quiescent conductive state is stable with the linear temperature profile $T_{\text{cond}}(z) = T_0 - \Delta T z/d$. In a mixture like, for example, ethanol dissolved in water, this conductive temperature gradient generates as a consequence of the Soret effect a concentration gradient, so that

$$C_{\text{cond}}(z) = C_0 + S_T C_0 (1 - C_0) \Delta T z/d. \quad (1)$$

Here, $C = \rho_1/(\rho_1 + \rho_2)$ is the mass concentration of the solute which is in our example the lighter component. C_0 is its mean, S_T the Soret coefficient, and $k_T = T_0 C_0 (1 - C_0) S_T$ the thermo-diffusion ratio. The Soret coupling between temperature and concentration fields (cf. below) is most conveniently measured in terms of the separation ratio $\psi = -S_T C_0 (1 - C_0) \beta/\alpha = -(k_T/T_0) \beta/\alpha$. Here, α and β are the thermal and solutal expansion coefficients of the total mass density $\rho_1 + \rho_2 = \rho = \rho_0 [1 - \alpha(T - T_0) - \beta(C - C_0)]$ of the mixture for small deviations of T and C from their means. Positive S_T corresponding to negative ψ (for mixtures such as ethanol-water where α and β are positive) implies a concentration increase (of the lighter component) near the cold upper plate and a decrease near the warmer lower plate and vice versa for $S_T < 0$ ($\psi > 0$). Note that in experiments, ψ can easily be varied, say, between -0.6 and 0.25 , by varying T_0 and C_0 .

Convection is described by the balance equations

$$\nabla \cdot \mathbf{u} = 0, \quad (2a)$$

$$(\partial_t + \mathbf{u} \cdot \nabla) \mathbf{u} = \sigma \nabla^2 \mathbf{u} + R \sigma (\delta T + \delta C) \mathbf{e}_z - \nabla p, \quad (2b)$$

$$(\partial_t + \mathbf{u} \cdot \nabla) T = \nabla^2 T, \quad (2c)$$

$$(\partial_t + \mathbf{u} \cdot \nabla) C = L \nabla^2 C - L \psi \nabla^2 T \quad (2d)$$

for mass (2a), momentum (2b), heat (2c), and concentration (2d) in the Oberbeck-Boussinesq approximation. δT and δC in (2b) denote deviations from the mean T_0 and C_0 , respectively. Lengths are scaled with d , time with the vertical thermal diffusion time d^2/κ , and the velocity field $\mathbf{u} = (u, v, w)$ with κ/d , where κ is the thermal diffusivity of the mixture. Temperatures are reduced by ΔT , concentration by $\Delta T \alpha/\beta$, and pressure p by $\rho_0(\kappa/d)^2$.

The Dufour effect that provides a coupling of concentration gradients into the heat balance is discarded because it is relevant only in a few gas

mixtures and possibly in liquid mixtures near the liquid–vapor critical point.

Besides the Rayleigh number $R = (\alpha g d^3 / \nu \kappa) \Delta T$ measuring the thermal driving force, three additional numbers enter into the field equations: the Prandtl number $\sigma = \nu / \kappa$, which is of order 10 for ethanol–water mixtures at room temperature, the Lewis number $L = D / \kappa \simeq 0.01$, and the separation ratio ψ . Here, ν denotes the kinematic viscosity and D the concentration diffusivity.

The concentration field is responsible for the significantly larger complexity of binary mixture convection compared with pure fluids. It causes the richness of spatiotemporal properties of the convective structures, of the bifurcation behavior, and of the transient growth of convection. The Soret-generated concentration variations δC influence the buoyancy, that is, the driving force for convective flow in (2b). The flow in turn mixes by advectively redistributing concentration. This nonlinear advective mixing in developed convective flow is typically much larger than the smoothing by linear diffusion—the Péclet number measuring the strength of advective concentration transport relative to diffusion is easily of the order of a few thousand. Thus, the concentration balance is strongly nonlinear giving rise to boundary layer behavior and strongly anharmonic concentration field profiles in the horizontal direction, as in Figure 1. In contrast, the momentum and heat balances remain weakly nonlinear close to onset as in pure fluids, implying only smooth and basically harmonic variations, $\sim e^{ik \cdot x}$, as the critical modes (cf. Figure 1).

To summarize, the feedback interplay among (i) the Soret-generated concentration variations that are sustained against mixing and diffusion by externally imposed and internal temperature gradients, (ii) the resulting changes in the buoyancy, and (iii) the strongly nonlinear advective transport and mixing causes binary mixture convection to be rather complex not only with respect to its spatiotemporal properties but also concerning its bifurcation behavior.

Take, for example, $\psi < 0$, where the Soret-induced separation requires higher heating to destabilize the conductive state than for a pure fluid characterized by $\psi = 0$ (for a review of the multitude of convection states appearing for destabilizing positive ψ see, for example, Huke et al., 2000). Then the off-diagonal coupling between solutal buoyancy and advection of Soret-induced concentration variations described above generates oscillations—traveling waves (TWs) of horizontally propagating rolls occur via a subcritical Hopf bifurcation whenever ψ is sufficiently negative. The bifurcation properties of such oscillatory TW states are shown in Figure 2 for different ψ as a function of the reduced Rayleigh number $r = R/R_c^0$, where $R_c^0 = 1707.76$ marks the convective onset in pure fluids. With increasing flow intensity (Figure 2a), the fluid gets

Figure 1. Evolution of convection after perturbing the quiescent conductive state. The concentration distribution in a vertical cross section of the fluid layer is displayed by color-coded plots where highest concentration was initially at the top, and lowest at the bottom. Wave profiles at midheight, $z=0$, are shown for the fields of vertical velocity w (thin lines), $400\delta T$ (lines with triangles), and $400\delta C$ (lines with squares). The final TW propagates to the left. Parameters are $L=0.01$, $\sigma=10$, $\psi=-0.25$, $r=1.42$, and wavelength $\lambda=2$. For better visibility two wavelengths are shown. (This figure is also reproduced on page 3 of the color plate section.)

more mixed while simultaneously the TW frequency decreases (Figure 2b) as the flow intensity and the Nusselt number (Figure 2d) approach the pure fluid reference values. Here the mixing is measured by the reduced spatial variance $M = \sqrt{\langle \delta C^2 \rangle / \langle \delta C_{\text{cond}}^2 \rangle}$ of the concentration.

Figure 1 shows the complex spatiotemporal concentration redistribution during the growth of oscillatory convection at slightly supercritical heating. The growth starts generically from perturbations of the conductive state that contain the two critical Hopf modes for counterpropagating TWs with roughly equal amplitudes. First, they linearly superimpose to form SW-like oscillations of growing amplitude with the large Hopf frequency. But then they compete via nonlinear advection with each other; at a critical SW amplitude, advective breaking of the concentration wave triggers a very fast flow-induced transition from SW to TW convection with anharmonic profile, large phase velocity, and large amplitude of the concentration wave. Finally, advective mixing and diffusive homogenization slow down the TW as the concentration differences between left and right turning rolls slowly decrease.

In mixtures with sufficiently negative ψ , there are also uniquely selected stable LTW states of

Figure 2. TW-bifurcation diagrams for different Soret coupling strength ψ : (a) squared maximal vertical flow $w_{\max}^2$, (b) frequency ω , (c) degree of mixing $1 - M$, and (d) convective contribution to the Nusselt number $N - 1$ vs reduced Rayleigh number r . Stable (unstable) TW states are marked by filled (open) symbols. Arrows mark Hopf thresholds r_{osc} for onset of TW convection. The $\psi = 0$ pure fluid limit is included in (a) and (d) by the dashed line. TW states on the vertical line are discussed in more detail in Hollinger et al. (1997). Only states in the shaded region of (a) are weakly nonlinear. Parameters are $L = 0.01$, $\sigma = 10$, and $\lambda = 2$.

localized, that is, spatially confined, TWs. They occur at small subcritical heating where extended TWs cannot exist and where the conductive state is strongly stabilized by the Soret effect. Such a strongly nonlinear LTW (Figure 3) is robustly sustained by a complex concentration redistribution process. Therein flow-induced mixing locally reduces the Soret separation and thereby increases the buoyancy to levels that suffice to drive well-mixed fluid flow there. In Figure 3, positive (negative) δC is sucked from the top (bottom) boundary layer into right (left) turning rolls as soon as they become nonlinear under the trailing LTW front. This happens when the vertical velocity w roughly exceeds the local phase velocity v_p (left arrow in Figure 3b) so that regions with closed streamlines appear (Hollinger et al., 1997; Lücke et al., 1998). Within them “dark” (“gray”) concentration is transported predominantly in the upper (lower) part of the layer to the right. Mean concentration, on the other hand, migrates mostly to

Figure 3. Broad LTW of length $l = 17.4$: (a) Concentration deviation δC from global mean (pale gray) in a vertical cross section of the layer. (b) Lateral wave profiles at midheight, $z = 0$, of δC (gray), vertical velocity w (black), and its envelope. At the arrows, $w_{\max} = v_p$. (c) Mixing number M (gray) and phase velocity v_p (black). The variation of the wavelength $\lambda(x) = 2\pi v_p(x)/\omega$ is the same because the LTW frequency ω is a global constant. (d) Time averaged deviations from the conductive state at $z = -0.25$ for concentration (upper), temperature (lower), and their sum (b) measuring the convective contribution to the buoyancy. (e) Streamlines of time averaged concentration current $\langle \mathbf{J} \rangle = \langle u\delta C - L\nabla(\delta C - \psi\delta T) \rangle$ (gray) and velocity field $\langle \mathbf{u} \rangle$ (black). The latter results from $\langle b \rangle$ and documents roll shaped contributions of $\langle u \rangle \langle \delta C \rangle$ to $\langle \mathbf{J} \rangle$ under the fronts and the associated $\langle \delta C \rangle$ redistribution. Thick black and gray arrows indicate $\langle \mathbf{u} \rangle$ and transport of positive δC (alcohol surplus), respectively. Thus, in the lower half of the layer, negative δC (water surplus) is transported to the right. Parameters are $L = 0.01$, $\sigma = 10$, $\psi = -0.35$, $r = 1.346$. (This figure is also reproduced on page 3 of the color plate section.)

the left along open streamlines that meander between the closed roll regions and that follow the global mean in Figure 3a. The time-averaged current of δC (gray lines in Figure 3e) reflects the mean properties of this transport. Since positive and negative (zero) δC is transported away from (towards) the left trailing front, mean concentration accumulates there and causes a strong drop of $M(x)$. In the same way, the leading front's concentration varies and with it, $M(x)$ are strongly increased even beyond the conductive state's values. Thus, unlike TWs, LTWs do not reach a balance among δC injection, advective mixing, and diffusive homogenization on a constant level of small M . Rather LTW rolls collapse under the leading front when v_p has grown up to w (right arrow in Figure 3b). Thereafter, concentration is discharged and sustains ahead of the leading front a barrier of $\langle \delta C \rangle$ that prevents the expansion of the conductive state into the LTW.

THETA FUNCTIONS

The n -dimensional *theta function* is a function of $n + n(n + 1)/2$ complex variables, $\theta(\mathbf{z}|\tau)$. The first n coordinates form a vector in an n -dimensional complex space $\mathbf{z} = (z_1, \dots, z_n)$ while the remaining $n(n + 1)/2$ variables are entries in a symmetric n -dimensional matrix τ_{ik} ; ($i, k = 1, \dots, n$). The theta function is defined by a Fourier series as

$$\theta(\mathbf{z}|\tau) = \sum_{\mathbf{m} \in \mathbb{Z}^n} e^{i\pi \mathbf{m} \tau \mathbf{m}' + 2i\pi \mathbf{z} \mathbf{m}'},$$

where the n -tuple summation runs over the whole n -dimensional set of integers $\mathbb{Z}^n$, and the imaginary part of the matrix τ is supposed to be positive definite to provide convergence of the series. The defining properties of the theta function are its periodicity and modular properties. The periodicity property is given by the relation

$$\begin{aligned} \theta(\mathbf{z} + \mathbf{e}_k|\tau) &= \theta(\mathbf{z}|\tau), \quad \theta(\mathbf{z} + \mathbf{e}_k \tau|\tau) \\ &= e^{-i\pi \tau_{kk} - 2i\pi \tau_{k\ell} \theta(\mathbf{z}|\tau)}, \quad k = 1, \dots, n, \end{aligned}$$

where only the k th component of the vector $\mathbf{e}_k$ is non-zero and equal to unity.

Consider the modular group Γ the group of all $2n \times 2n$ integer matrices γ such that $\gamma J \gamma' = J$ where

$$J = \begin{pmatrix} 0 & -1_n \\ 1_n & 0 \end{pmatrix},$$

and 1_n is the unit n -dimensional matrix. Under the action of the modular group, the theta-function transforms as

$$\begin{aligned} \theta(\mathbf{z}|\tau) &= \frac{\varepsilon}{\sqrt{\det M(\tau)}} \\ \exp \left\{ \frac{1}{2} \sum_{i,k=1}^n z_i z_k \frac{\partial}{\partial \tau_{ik}} \det M(\tau) \right\} &\theta(\mathbf{z}'|\tau'), \end{aligned}$$

where

$$\begin{aligned} M(\tau) &= c\tau + d, \quad \mathbf{z}' = (a\tau + d)^{-1} \mathbf{z}, \\ \gamma &= \begin{pmatrix} a & b \\ c & d \end{pmatrix}, \\ \tau' &= (a\tau + b)(c\tau + d)^{-1}, \end{aligned}$$

a, b, c, d are $n \times n$ matrices and $\varepsilon^8 = 1$.

The theta functions are introduced to construct modular functions in τ -variables of order k defined to satisfy $f(\gamma \circ \tau) = \det(c\tau + d)^k f(\tau)$ and abelian functions in $\mathbf{z}$ -variables. Abelian functions $F(\mathbf{z})$ are functions of n complex variables with $2n$ complex periods, T_i , $i = 1, \dots, 2n$, $F(\mathbf{z} + T_i) = F(\mathbf{z})$. The advantage of using theta functions to define modular and abelian functions comes from the rapid convergence of the *theta-series*.

The most important class of abelian functions are abelian functions whose τ -variables are constructed from an algebraic curve X of genus n , given by a polynomial equation $P(\lambda, \mu) = 0$. The introduction of local coordinates turns X into a one-dimensional complex analytical variety called the Riemann surface of the curve X . The Riemann surface of genus n can be topologically described as a sphere with n handles. It is always possible to draw, on such a torus, a basis of $2n$ -cycles $a_1, \dots, a_n; b_1, \dots, b_n$ with intersection numbers $a_i \circ a_j = b_i \circ b_j = 0$ and $a_i \circ b_j = -b_j \circ a_i = \delta_{ij}$, where $\circ$ means intersection of corresponding cycles.

Differential and integral calculus can also be developed on X . In contrast to the case of an extended complex plane, or Riemann sphere, which can be considered as a Riemann surface of genus zero, there exists n linearly independent holomorphic differentials $dw_1, \dots, dw_n$ which can be normalized by the conditions $\oint_{a_k} dw_i = \delta_{ik}$. The period matrix τ of the curve is then given by $\tau_{ik} = \oint_{b_i} dw_k$. Meromorphic differentials $d\omega_k$, that is, differentials with poles of order k ,

can be also defined on X ; usually these differentials are normalized by the condition $\oint_{a_l} d\omega_k = 0, l = 1, \dots, n$.

The abelian function $u(t) = u(t_1, \dots, t_n)$ of n complex variables associated with the curve X of genus n is then defined as

$$u(t_1, \dots, t_n) = -2 \frac{\partial^2}{\partial t_1^2} \log \theta \left(\sum_{k=1}^n U_k t_k + U_0 \tau \right) + c, \quad (1)$$

where the vector U_k is the vector of b -periods of the normalized meromorphic differential $d\omega_k$, U_0 is a vector through which initial data are introduced and c is a constant.

The most developed case is the case of hyperelliptic curves, when the polynomial P is given by

$$P(\lambda, \mu) = \mu^2 - \prod_{k=1}^{2n+1} (\lambda - \lambda_k),$$

where n is the genus and the branching points $\lambda_k, k = 1, \dots, 2n+1$ are supposed to be distinct. The holomorphic differentials described above are given in this case by the formula $d\omega_k = \lambda^{k-1} d\lambda / \mu, k = 1, \dots, n$. In the case $n = 1$, the abelian function of the curve is the well-known elliptic function.

The remarkable role of θ functions in the spectral theory of the Schrödinger equation was discovered by Its & Matveev (1975). Consider the spectral problem

$$\left\{ \frac{\partial^2}{\partial x^2} - u(x) \right\} \Psi(x; \lambda, \mu) = \lambda \Psi(x; \lambda, \mu),$$

where $u(x)$ is smooth and real potential, $\Psi(x; \lambda, \mu)$ is an eigenfunction, and λ is the spectral parameter. Suppose that the spectrum consists of $n+1$ continuous segments $[\lambda_1, \lambda_2], \dots, [\lambda_{2n+1}, \infty]$. Then the potential is given by the formula (1) with $t_1 = x$ and $t_k = \text{const}$ for $k > 1$, while the eigenfunction $\Psi(x; \lambda, \mu)$ is given by the formula

$$\Psi(x; \lambda, \mu) = C \frac{\theta \left(\int_{(\infty, \infty)}^{(\lambda, \mu)} d\mathbf{w} + U_2 x + U_0 \tau \right)}{\theta(U_2 x + U_0 \tau)} \times \exp \left\{ x \int_{(\lambda_0, \mu_0)}^{(\lambda, \mu)} d\omega_2(\lambda, \mu) \right\}, \quad (2)$$

where C is a normalizing constant, $d\omega_2(\lambda, \mu)$ is the second kind abelian differential with second-order pole at infinity and zero a_i -periods, U_2 is a vector of b_i -periods of $d\omega_2(\lambda, \mu)$, and the constant vector U_0 and point (λ_0, μ_0) are defined by initial conditions. The isospectral deformation of the potential $u(x)$ when the second variable $t_2 = t$ in formula (1) is switched on, while other variables $t_k, k > 2$ remain constant, turns the function $u(x, t)$ into the n -gap solution of

the Korteweg-de Vries equation. Equations (1) and (2) form the foundation of the theory of finite-gap solutions of soliton equations. In the limit when the branch points collide in pairs, $\lambda_{2k-1} \rightarrow \lambda_{2k}, k = 1, \dots, n$, these formulae become N -soliton formulae. Krichever (1977) generalized the whole theory to other soliton equations and nonhyperelliptic curves.

Introductions to the subject are given in Farkas & Kra (1998) for the theory of Riemann surfaces, Novikov, Chapter 11 in Zakharov et al. (1980), Dubrovin (1981), Mumford (1983, 1984) for theta functions and completely integrable equations, and Belokolos et al. (1994) for algebro-geometric methods of integration of nonlinear equations.

THRESHOLD PHENOMENA

Defined in the dictionary as an “intensity below which a mental or physical stimulus cannot be perceived and can produce no response,” the term *threshold* has deep roots in our language, representing a collective awareness of strong nonlinearity. Above threshold, the effect of a stimulus changes dramatically from that below, as is indicated by such common phrases as the “tipping point” and the “last straw.” Examples of threshold phenomena abound in physics, engineering, nonlinear mathematics, chemistry, biology, and neuroscience.

Applications of the Threshold Concept

In nonlinear optics, the threshold for laser oscillation specifies a level of pump power below which only a small amount of incoherent light is emitted from the laser, while above threshold a brilliant, highly directed beam of output light is observed. Beginning with the wall switch, electrical engineers have devised many varieties of threshold circuits that change rapidly from one voltage level to another when an input variable exceeds a certain value; indeed, a digital computer can be viewed as a large collection of interacting threshold devices. Also the threshold logic unit (TLU), comprising a switch with input channels having adjustable weights, is a useful component of learning systems for pattern recognition (Nilsson, 1990).

Figure 1. A Heaviside step function.

Mathematical representations of switching devices often involve the Heaviside step function,

$$H(x - x_0),$$

a generalized function that is zero for $x < x_0$ and one for $x > x_0$, where x_0 is the threshold as shown in Figure 1. In phase space models of nonlinear dynamic systems, one often finds a *separatrix*, or critical surface across which solution trajectories have very different behaviors. Noting this, mathematician cum meteorologist Edward Lorenz famously asked: "Does the flap of a butterfly's wings in Brazil set off a tornado in Texas?"—not only coining a dramatic metaphor for threshold phenomena and launching modern studies of chaos, but also leading philosophers to examine what is meant by causality. Is it only the *last* straw that should be blamed for breaking the camel's back? Or are *all* the straws that were loaded onto the beast to some degree complicit?

In the realms of physical chemistry, a reaction-diffusion (excitable) system rests quietly until stimulated above its threshold for self-supporting activity, whereupon traveling waves, spirals, and scroll waves are typically observed to emerge. In biology, examples of threshold phenomena include the germination of a seed at a critical (threshold) level of ambient moisture and the insemination of an ovum, in addition to the birth of life itself from the chemical components of the Hadean oceans some 3.5 billion years ago.

Figure 2. Threshold action in a branching region of a squid giant axon. The interpulse interval is slightly longer in (c) than in (b).

Threshold Effects in Neuroscience

As one would suppose from introspection, the field of neuroscience offers many examples of threshold phenomena which have become known since the observation of "all-or-none" response of a neuron was proposed by Edgar Adrian in 1914 (Adrian, 1914). This threshold behavior of a neuron was used by psychiatrist Warren McCulloch and mathematician Walter Pitts in 1943 to formulate the first computer model of the human brain McCulloch & Pitts (1943). Their model assumes each neuron to be represented by a single Heaviside step function, which jumps from the off (zero) to the on (one) state when a linear sum of input (dendritic) signals exceeds a threshold value. In 1958, Frank Rosenblatt introduced the "perceptron" which employs TLUs as the basic elements of a brain model (Rosenblatt, 1958).

Recent studies of dendritic dynamics suggest far greater complexity, with the possibility of threshold effects occurring at the branching regions of incoming fibers (Stuart et al., 1999). In Figure 2 are displayed some experimental measurements of nerve impulse transmission through a branching region in the giant axon of a squid (Scott, 2002). Figure 2(a) shows the geometry of the preparation (not to scale), indicating the electrode positions where upstream (B) and downstream (A) recordings were made. The preparation was stimulated with two pulses, which are seen in the upper traces of both Figures 2(b) and 2(c). In these experiments, the spacing between the two incoming impulses was under experimental control, and below a certain threshold value of this impulse interval—that shown in Figures 2(b) and 2(c)—it is seen that the second impulse no longer makes it through. Besides interpulse interval, several other neural parameters can result in such a threshold effect, including branch geometry, ionic concentrations, fatigue, and narcotization level.

As the dendrites of many neurons are known to carry active impulses (action potentials) (Stuart et al., 1999), it appears that the branching regions of dendrites can act as threshold devices (switches), greatly increasing our estimates of the ability of a neuron to process information (Scott, 2002).

TIME-SERIES ANALYSIS

Predicting total eclipses of the moon or the sun is an art that dates back to mankind's oldest civilizations. Nonetheless, it represents a class of very modern analytic tools: the analysis of time-series data. A time-series is a set of measurements s_n , $n = 1, \dots, T$, whose index n refers to the time t when the measurement is recorded by $n\tau = t$, τ is the sampling interval. For time-dependent phenomena, this index carries part of the information which is destroyed, for example, by a random reshuffling of the temporal order of the measurements. If one wishes to make use of this property in data analysis, particular statistical methods are required which are able to characterize temporal correlations inside the data. Typical goals in time-series analysis are predictions, data classification, signal manipulation, and system identification.

Today's technical facilities for data acquisition and data storage call for efficient time-series tools. To mention a few examples, in medicine (particularly cardiology and neurology), there is a need for automated diagnostics (i.e., data classification). In finance or weather and climate research, data-driven prediction methods are relevant, since model equations are either lacking (economy) or expensive to solve (weather). In modern telecommunications and automatic speech recognition, noise reduction is an essential issue, where time-series analysis should supply the background for signal separation.

The above examples show that unlike data of the positions of the planets, whose analysis enabled Johannes Kepler to derive the laws of planetary motion, modern time-series problems are concerned with data that have a complicated, strong aperiodic component. All data analysis methods start from some paradigm about the origin of the observed signatures and irregularities. This background is indispensable for a sound interpretation of the statistical quantities thus obtained, or for an estimate of the validity of the consequences drawn from the results. However, the large number of different approaches in time-series modeling supplies a corresponding diverse set of time-series analysis methods. We focus here on the two most general approaches, both of which represent a whole theoretical framework and not just a particular aspect.

Linear stochastic models are a well-developed class of time-series models. Being linear, their properties

can be fully and rigorously derived from their model equations. However, in order to generate aperiodic time-series data, such models require stochastic inputs. Auto regressive models AR(M),

$$s_{n+1} = \sum_{k=0}^{M-1} a_k s_{n-k} + \xi_n,$$

where ξ_n is Gaussian distributed white noise ($\langle \xi_i \xi_m \rangle = \delta_{i,m}$) with unit variance, represent the time discretized motion of the superposition of $M/2$ damped harmonic oscillators driven by noise, if the coefficients a_k fulfill certain stability conditions. The output is therefore characterized by $M/2$ frequencies and the corresponding damping coefficients, such that a spectral analysis is the most suitable analysis tool (See **Spectral analysis**). Thus, AR-models are suitable for data sets that have a few pronounced peaks in their power spectrum. If the observed power spectrum instead is broad band, another linear model, the moving average model MA(N), can be more reasonable:

$$s_{n+1} = \sum_{k=0}^{N-1} b_k \xi_{n-k},$$

where ξ_n is again white Gaussian noise. Notice that there is no feedback of the observable s , so that this model just averages over the independent noise inputs and hence creates colored noise. In the limits $N, M \rightarrow \infty$, both model classes are equivalent. For practical purposes where a small number of coefficients is desirable, a combination of both, the ARMA(M,N)-model, is often used. The coefficients of such models can be fit to observed data, for example, by solving least-squares problems (Box & Jenkins, 1976).

The well-known sunspot number time series of solar activity with its pronounced 11-year period can be well captured by an AR-model. ARMA models are also rather suited to describe many noise-dominated signals such as sound emission signals in technical environments, and they are used to model single phonemes of human speech in automatic speech recognition systems. ARMA-models are hence employed for data-driven predictions and signal classification tasks. They are often useful if the signal is either dominated by some few frequencies or when it is really noisy. However, the linearity of the model behind translates into the fact that the observables should be Gaussian random variables themselves, and that all higher-order statistics beyond the power spectrum and the auto-correlation function are fully determined by either of these two.

From many model systems and physical laboratory experiments arises a different class of sources for aperiodic time-series data: so-called chaotic dynamical systems. Aperiodicity here comes from intrinsic instabilities without random inputs, and nonlinearity

Figure 1. Sketch of the time-delay embedding procedure: The time series s_n (plotted in the frontal plane) combined with its time shifted version (in the bottom plane) forms a sequence of vectors (the curve in space), whose projection along the time axis accumulates to a set of points representing (in this particular case) a strange attractor together with an invariant measure on it. The data are voltages measured in a chaotic electric resonance circuit.

destroys the superposition principle, such that a Fourier decomposition of the signal is not useful. Higher-order statistics is not trivially related to second-order statistics. Instead of a statistical characterization, one would here try to reconstruct the deterministic and dynamic origin of the signal.

If one assumes that a given experimental observable represents the deterministic dynamics in some non-observed and even unknown phase space, the concept of phase space reconstruction by embedding is needed: As proven by Takens (1981), the set of delay vectors obtained from a scalar time series by joining successive observations, $s_n = (s_n, s_{n-1}, s_{n-2}, \dots, s_{n-m+1})$, is equivalent to a set of phase space vectors of the underlying dynamical system, provided that the embedding dimension m fulfills $m > 2D_f$ (see Figure 1). Here, D_f is the attractor dimension of the underlying dynamical system (See **Attractors; Dimensions; Fractals**). Hence, successive vectors s_n are deterministically related to each other by an unknown function $s_{n+1} = F(s_n)$, which reduces to an unknown scalar function $s_{n+1} = f(s_n)$, since the other components of s_{n+1} are just copied from s_n .

In a practical analysis, one represents the time-series data in embedding spaces with increasing dimension m and searches for signatures of determinism. One model free approach for this is the estimation of the fractal dimension of the set of delay vectors in the embedding space, which should saturate at the value D_f for $m > D_f$. Of interest is predictability: one can try to extract the unknown function $f(s_n)$ from the time series, by selecting a suitable model for f and then solving the least-squares problem $\sum (s_{n+1} - f(s_n))^2 = \min$, where the minimization is done with respect to parameters in f . In the simplest case, f is approximated by a constant in a neighborhood of the actual observation s_n . Then, the predictor is the average over the future values of all neighboring vectors

s_k of s_n , $\hat{s}_{n+1} = \langle s_{k+1} \rangle$, where $\|s_k - s_n\| < \varepsilon$ with some suitable norm and some suitably small ε (also called the “Lorenz method of analogues”). Regardless of how the function f is represented, the relation $\hat{s}_{n+1} = f(s_n)$ will yield only good predictions for s_{n+1} if the embedding dimension m is large enough for the delay vectors to be equivalent to the unknown phase space vectors of the underlying dynamical system. In such an embedding space, the delay vectors form a finite sample according to the underlying invariant measure of the dynamical system, so that, in principle, all characteristics of the latter (Lyapunov exponents, entropies) can be determined (See **Chaotic dynamics**).

Such methods have been successfully applied to many physical laboratory experiments, but more recently successful applications to real-world data have been reported, such as noise reduction for human voice, wind speed prediction for wind farms, diagnostics on human heart rate data, epilepsy prediction, and machine wear detection in technical production systems. The extension of the theory to noise-driven nonlinear systems and to nonstationary data has recently been tackled, but highly nonrecurrent data such as economics data will probably remain untractable.

TODA LATTICE

The Hamiltonian system governing the longitudinal oscillations of a chain of unit point masses connected by identical springs is

$$\begin{aligned} \dot{q}_n &= \dot{p}_n, \\ \dot{p}_n &= V'(q_{n+1} - q_n) - V'(q_n - q_{n-1}), \end{aligned} \quad (1)$$

where $-V'$ is the restoring force of the springs and q_n is the displacement of the n th mass from equilibrium. Morikazu Toda (Toda, 1981) introduced the potential (scaled here so that two physical parameters disappear)

$$V(r) = e^{-r} + r - 1, \quad (2)$$

and discovered explicit solutions of (1). He obtained periodic traveling waves, in terms of elliptic functions, and two-soliton solutions in terms of sech^2 . (The term $(r-1)$ makes $V(r) \sim r^2/2$ for small r ; it cancels out in the problems considered below.)

This mass-spring chain is the Toda lattice. It is valuable as a solvable model of one-dimensional lattice dynamics; it is frequently used to illustrate fundamental constructions common to many integrable systems; and it appears, sometimes in surprising ways, in a variety of physical and mathematical problems.

The Infinite and Periodic Lattices

All the special properties of the Toda lattice flow from a Lax representation, $\dot{L} = [B, L]$, which implies that eigenvalues and certain other spectral data of L are independent of time. For many purposes, it is convenient to write L and B in new coordinates. With the definition

$$a_n = \frac{1}{2} e^{-(q_{n+1} - q_n)/2}, \quad b_n = \frac{1}{2} p_n, \quad (3)$$

the exponential nonlinearity in (2) becomes polynomial:

$$\dot{a}_n = a_n(b_n - b_{n+1}), \quad \dot{b}_n = 2(a_{n-1}^2 - a_n^2). \quad (4)$$

The standard Poisson bracket on q_n, p_n induces a (nonstandard) Poisson bracket on a_n, b_n , in which the only nonzero relations are

$$\{a_n, b_n\} = -\frac{1}{4}a_n, \quad \{a_n, b_{n+1}\} = \frac{1}{4}a_n. \quad (5)$$

The Lax operators are discretized Schrödinger operators with potentials a_n, b_n , acting on sequences $y = (\dots, y_{-1}, y_0, y_1, \dots)$:

$$\begin{aligned} (Ly)_n &= a_{n-1}y_{n-1} + b_n y_n + a_n y_{n+1}, \\ (By)_n &= a_{n-1}y_{n-1} - a_n y_{n+1}. \end{aligned} \quad (6)$$

A (finite or infinite) tridiagonal symmetric matrix, such as L , is called a “Jacobi matrix.” In terms of the shift operator $\Delta z_n = z_{n+1}$, which is a convenient abbreviation,

$$L = \Delta^{-1}a + b + a\Delta, \quad (7)$$

where a and b are the diagonal matrices $\text{diag}(a_n)$, $\text{diag}(b_n)$. Constants of motion derived from the Jacobi operator L will be in involution, that is, they have zero Poisson bracket.

Thanks to its Lax representation, methods used in the study of other soliton equations also apply to the Toda lattice.

The Bi-infinite Lattice with Decaying Initial Condition (Toda, 1981)

According to (3), $(q_{n+1} - q_n) \rightarrow 0$ and $p_n \rightarrow 0$ translates to $a_n \rightarrow \frac{1}{2}$, $b_n \rightarrow 0$. The initial value problem is studied by a discrete version of the inverse scattering method. The unperturbed eigenvalue operator at $n = \pm \infty$ is $L_0 = \frac{1}{2}(\Delta^{-1} + \Delta)$, which has the bounded “plane wave” eigenfunctions $y_n = z^{\pm n}$, $|z| = 1$, for $\lambda = (z + z^{-1})/2 \in [-1, 1]$. This relation between “energy” λ and “momentum” z is the analog of $\lambda = k^2$ in the Schrödinger equation. The scattering matrix is a function of momentum and is defined on $|z| = 1$. Bound states may occur for $\lambda < -1$ and $\lambda > 1$; these correspond to solitons moving to the left and to the right, respectively. In the absence of solitons (and with a certain condition on the reflection coefficient), the large-time behavior consists of a decaying wave train for $|n/t| < 1$, vanishingly small motion when $|n/t| > 1$, and a connecting regime described by a Painlevé transcendent (Kamvissis, 1993).

Constants of motion of the infinite lattice can be computed explicitly as $I_k := \text{Trace} \frac{1}{k}(L^k - L_0^k)$ (L_0^k removes a divergent term). The Hamiltonian equations generated by the I_k are found by use of the Poisson bracket (5).

The Periodic Lattice (Toda, 1981)

The potential in the Lax operator is periodic, say, period N . As in the theory of Hill’s equation, one introduces a Floquet multiplier and Floquet solutions by imposing the condition

$$y_{N+n} = \rho y_n. \quad (8)$$

L and B then reduce to matrices:

$$L(\rho) = \begin{pmatrix} b_1 & a_1 & 0 & \dots & \rho^{-1} a_N \\ a_1 & b_2 & a_2 & \dots & 0 \\ 0 & a_2 & \ddots & \ddots & \vdots \\ \vdots & & \ddots & \ddots & a_{N-1} \\ \rho a_N & \dots & \dots & a_{N-1} & b_N \end{pmatrix}, \quad (9)$$

$$B(\rho) = \begin{pmatrix} 0 & -a_1 & 0 & \dots & \rho^{-1} a_N \\ a_1 & 0 & -a_2 & \dots & 0 \\ 0 & a_2 & \ddots & \ddots & \vdots \\ \vdots & & \ddots & \ddots & -a_{N-1} \\ -\rho a_N & \dots & \dots & a_{N-1} & 0 \end{pmatrix}. \quad (10)$$

The parameter ρ cancels from the Lax equation. The characteristic polynomial $\det(L(\rho) - \lambda I)$ is a rational function whose coefficients are independent of time. The function $\rho(\lambda)$ obtained by solving the characteristic equation for ρ is defined on the λ -plane with branch

cuts, and determines a compact Riemann surface. For Toda’s traveling wave, there are only two branch cuts; this fact is responsible for the occurrence of elliptic functions in his solution formula.

Every energy surface is compact, so that the solution curves lie on tori; abstractly, these are the (real) Jacobian varieties associated with the Riemann surface. Action variables can be written explicitly as loop integrals. The solution of the periodic Toda lattice is expressed in terms of theta functions.

The Free Toda Lattice and Lie Theory

Many features common to integrable systems are illustrated by an example due to Jürgen Moser.

The Free Toda Lattice (Toda, 1981)

Particles number 0 and $(N+1)$ are pulled to $-\infty$ and $+\infty$, respectively. (3) implies that $a_0 = a_N = 0$, and the corner entries in $L(\rho)$ and $B(\rho)$ disappear. The resulting matrices will be written simply as L, B .

Springs governed by potential (2) resist compression and are encouraged to expand. Therefore, there will now be no confining force on the remaining springs. The masses move apart as $t \rightarrow \pm\infty$, and behave asymptotically like free particles. As $t \rightarrow \pm\infty$, $(q_{n+1} - q_n) \rightarrow \infty$, whence $a_n \rightarrow 0$, the matrix $L(t)$ becomes diagonal, and the entries $b_n = p_n/2$ approach the eigenvalues of $L(0)$. Thus, the eigenvalues are the momenta of the free particles. As $t \rightarrow -\infty$, these are arranged with the slowest particle farthest to the right; after interaction and a phase shift, the particles emerge as $t \rightarrow +\infty$ with the fastest to the right. This is soliton interaction reduced to bare essentials. The diagonalization of $L(t)$ as $t \rightarrow +\infty$, with the eigenvalues (momenta) ordered, is called the “sorting property,” and points to a connection between isospectral flows and numerical linear algebra.

For tridiagonal L , the number of eigenvalues is exactly half the number of entries, and they suffice for integrability. Remarkably, the Lax equation $\dot{L} = [B, L]$ (with appropriate B), is completely integrable even when L is a generic symmetric matrix. The additional constants of motion required are constructed in Deift et al. (1986). The sorting property again holds; it is related to the QR diagonalization algorithm in numerical linear algebra.

The free Toda lattice is perhaps the simplest integrable system with a clear Lie-algebraic generalization. If one sets $\text{Trace } L = 0$ in (9), that is, total momentum = 0, then L belongs to $\mathfrak{sl}_N$, the Lie algebra of $N \times N$ matrices with trace zero. Let $\{h_i\}$ be a basis for the diagonal matrices in $\mathfrak{sl}_N$. The matrices $e_{\pm i}$ with a single 1 in the $(i, i+1)$, resp. $(i+1, i)$ entry, and zeros elsewhere, are called “raising and lowering operators.” There are analogs of $e_{\pm i}, h_i$ in the class of split real semisimple Lie algebras, such as the algebra

of symplectic matrices. The Lax pair, written as

$$\begin{aligned} \mathbf{L} &= \sum_{i=1}^{N-1} [\beta_i h_i + a_i (e_i + e_{-i})], \\ \mathbf{B} &= \sum_{i=1}^{N-1} a_i (-e_i + e_{-i}), \end{aligned}$$

makes sense in those algebras. In the corresponding generalized mass–spring systems, some particles will be governed by modifications of (2) (Olshanetsky & Perelomov, 1994; Guest, 1997; Reyman & Semenov-Tyan-Shansky, 1994; Semenov-Tyan-Shansky, 1994 a,b).

The extension to Lie algebras is not just generalization for sake of generalization. It illuminates concrete matrix calculations. There is an abstractly defined Poisson bracket, the Kostant–Kirillov bracket, of which (5) is a special case. Hamiltonian equations with respect to this Poisson bracket always have the Lax form, $\dot{X} = [Y, X]$. One of the fundamental properties of Lax equations, the representation of the solution by means of a factorization in the Lie group, is a general Lie-theoretic phenomenon that specializes to many different integrable systems and, in particular, yields involutivity of the constants of motion $\text{Trace } \mathbf{L}^k$ (Guest, 1997; Semenov-Tyan-Shansky, 1994 a,b).

For the free Toda lattice, the factorization method is simple linear algebra, but it already conveys the basic idea.

Here, as well as later, it is convenient to redefine

$$a_n = \exp(q_n - q_{n+1}), \quad b_n = -p_n. \quad (11)$$

In terms of the shift operator (7), $\mathbf{L}$ and $\mathbf{B}$ then become

$$\mathbf{L} = \Delta^{-1} a + b + \Delta, \quad \mathbf{B} = -\Delta^{-1} a. \quad (12)$$

($\mathbf{L} = b + \Delta$ or $\mathbf{B} = b + \Delta$ will give the same $\dot{\mathbf{L}}$.) Given the initial value $\mathbf{L}(0)$, write

$$\exp(t\mathbf{L}(0)) = n_{-}(t)^{-1} d(t) n_{+}(t) := n_{-}(t)^{-1} b_{+}(t) \quad (13)$$

with $n_{\pm(t)}$ upper/lower triangular having 1's on the diagonal and $d(t)$ diagonal; this is just Gaussian elimination. Then

$$\mathbf{L}(t) = b(t)\mathbf{L}(0)b(t)^{-1} \text{ satisfies } \dot{\mathbf{L}}(t) = [\mathbf{B}(t), \mathbf{L}(t)], \quad (14)$$

where $\mathbf{B}(t) = \mathbf{L}(t)_{+}$ is the upper triangular part of $\mathbf{L}(t)$.

Similarly, one finds the solutions of the Hamiltonian equations generated by the constants of motion I_{k+1} (referred to as “higher Toda flows”). One introduces a separate time variable t_k for each of these systems and now factors $\exp(t_k \mathbf{L}(0)^k)$. The resulting $\mathbf{L}$ satisfies

$$\frac{\partial \mathbf{L}}{\partial t_k} = [\mathbf{B}_k, \mathbf{L}], \quad \text{with } \mathbf{B}_k = (\mathbf{L}^k)_{+}. \quad (15)$$

($\mathbf{L}^k$ arises because $\nabla I_{k+1} = \mathbf{L}^k$). The simultaneous solution of (15) is a multi-parameter flow, $\mathbf{L}(t_1, \dots, t_{N-1})$, on phase space (t_1 is the original t). Compatibility of these equations, that is, equality of mixed partial derivatives of $\mathbf{L}$, is equivalent to the involutivity of the I_k . For an infinite lattice, there are infinitely many equations (15), and infinitely many time variables $\mathbf{t} = (t_1, t_2, \dots)$. Many soliton hierarchies have the same general form; for the higher KdV equations, for example, $\mathbf{L} = d^2/dx^2 + u(x)$ and $\mathbf{B}_k = (\mathbf{L}^{(2k+1)/2})_{+}$.

In Gaussian elimination, as in (13), d_{nn} is known to be τ_n/τ_{n-1} , where τ_n is the upper left $n \times n$ minor determinant of $\exp[t\mathbf{L}(0)]$. Tracing through the factorization steps, one finds the Hirota formula

$$a_n(t) = a_n(0) \frac{\tau_{n+1}(t) \tau_{n-1}(t)}{\tau_n(t)^2}, \quad (16)$$

which implies

$$a_n = \frac{d^2}{dt^2} \ln \tau_n, \quad b_n = \frac{d}{dt} \ln \frac{\tau_n}{\tau_{n-1}}.$$

These τ_n are prototypes of a fundamental object in the theory of soliton hierarchies, the “ τ -function,” which elsewhere occurs in far more complex settings.

The τ -functions have a representation-theoretic meaning. They are the matrix elements

$$\tau_n(t) = \langle \exp(t\mathbf{L}(0)) \mathbf{e}_1 \wedge \mathbf{e}_2 \wedge \dots \wedge \mathbf{e}_n \mid \mathbf{e}_1 \wedge \mathbf{e}_2 \wedge \dots \wedge \mathbf{e}_n \rangle \quad (17)$$

in the representation of the Lie group SL_N on the n^{th} exterior power of $\mathbb{R}^N$ (totally antisymmetric covariant tensors of order n). This formula gives precisely the $n \times n$ minor determinant of $\exp(t\mathbf{L}(0))$. The skew-vector $\mathbf{e}_1 \wedge \dots \wedge \mathbf{e}_n$ is the highest weight vector of the representation; it is annihilated by all raising operators. One may think of it as a vacuum vector and of (17) as a vacuum expectation value.

Loop Algebras and Affine Lie Algebras

The lower/upper factorization (13), solution (14), the τ -functions arising from the diagonal part in this factorization, and their interpretation in terms of group representations are fundamental features of integrable systems. The free Toda lattice affords a transparent illustration; more sophisticated versions of these ideas, set in other Lie algebras and groups, apply to a wide variety of equations. “Loop algebras” and “affine Lie algebras” are particularly useful in the theory of the periodic Toda lattice.

The loop algebra, $\widetilde{\mathfrak{sl}}_N$, is an infinite-dimensional Lie algebra whose elements are trace zero matrices $\mathbf{X}(\rho)$ with entries that are polynomials in ρ and ρ^{-1} . Such $\mathbf{X}(\rho)$ are called “loops,” because the mapping $\mathbf{X} : \{|\rho| = 1\} \mapsto \mathfrak{sl}_N$ gives a closed curve, that is, “loop,” of matrices. The Lie bracket is still the matrix commutator.

The Lax operators (9) and (10), for the periodic Toda lattice, belong to $\mathfrak{sl}_N$. To solve the periodic Toda lattice by factorization, one prescribes the initial value $\mathbf{A}(\rho)$ of $\mathbf{L}(\rho)$ and seeks matrix functions $g_{\pm}(t, \rho)$ for which

$$\exp(t\mathbf{A}(\rho)) = g_{-}(t, \rho)^{-1} g_{+}(t, \rho). \quad (18)$$

These $g_{\pm}(\cdot, \rho)$ are required to be analytic inside (resp. outside) the circle $|\rho| = 1$; this is the analog of lower/upper in (13). The eigenvector $v(\lambda, \rho(\lambda))$ of $\mathbf{A}(\rho)$, which is a function on the Riemann surface $\det(\mathbf{A}(\rho) - \lambda \mathbb{I}) = 0$, determines $g_{\pm}(t, \rho)$. The former is expressed in terms of theta functions; hence, so are $g_{\pm}$ and also $\mathbf{L} = g_{+} \mathbf{A} g_{+}^{-1}$ (Reyman & Semenov-Tyan-Shansky, 1994).

To obtain the τ -functions from a Lie algebra representation, one must introduce an extension of the loop algebra, the “affine” Lie algebra $\widehat{\mathfrak{sl}}_N$. (Affine Lie algebras give the name to affine Toda field theory, described below.)

The affine algebra has one extra element $\hbar$, which, in some respects, acts like an identity matrix. It has zero bracket with all loops; however, the ordinary matrix commutator in $\widehat{\mathfrak{sl}}_N$ is modified so that $\hbar$ can arise as a Lie bracket of loops. This would not be possible if $\hbar$ were truly the identity, since a matrix commutator $[\mathbf{X}(\rho), \mathbf{Y}(\rho)]$ must have trace zero. The extended algebra contains loops that behave as annihilation and creation operators: they satisfy $[a_k^*, a_k] = \hbar$. Thanks to this modification, the familiar realization of the Heisenberg commutation relations by multiplication and differentiation operators becomes available in the study of representations of $\widehat{\mathfrak{sl}}_N$.

The τ -functions for the periodic Toda lattice are obtained as vacuum expectation values, analogous to (17), in certain representations of the affine Lie algebra; they turn out to be theta functions and again satisfy the Hirota equations (16). For the free Toda lattice, τ -functions also arose from the diagonal factor in $n \cdots dn_{+}$. There is a similar factorization in the affine group $\widehat{SL}_N$. This group and the diagonal factor in the lower/upper factorization are rather complicated objects. In particular, the determinant of d will be an infinite determinant.

The matrices e_0 (resp. f_0) with the corner elements ρe_{N1} , resp. $\rho^{-1} e_{1N}$ in (9), (10) have an intrinsic meaning (they are raising resp. lowering operators in $\widehat{\mathfrak{sl}}_N$). Therefore, the periodic Toda lattice will generalize to the algebra of loops with values in a semisimple Lie algebra.

An affine Lie algebra also provides the setting for a remarkable unification of two of the most important soliton systems, the Toda lattice and the Ablowitz–Kaup–Newell–Segur (AKNS) equations. From the solution $a_n(\mathbf{t})$, $b_n(\mathbf{t})$ of the Lax equations (15) for the infinite lattice, one can build functions $q_n(\mathbf{t})$, $r_n(\mathbf{t})$, which, for every n , satisfy the general AKNS hierarchy, with t_1 playing the role of x . For example,

the simultaneous solution $a_n(t_1, t_3)$, $b_n(t_1, t_3)$ of the Toda equations and the higher Toda flow generated by $\text{Trace } \mathbf{L}^4$ will be transformed into solutions $q_n(x, t_3)$, $r_n(x, t_3)$ of the modified KdV (MKdV) equation. A kind of Bäcklund transformation (precisely, a Schlesinger transformation) connects q_n, r_n and $q_{n \pm 1}, r_{n \pm 1}$. As a special case, solutions of the free Toda lattice correspond to soliton-like potentials for AKNS.

This result can be obtained by operations on formal series, but the Lie-theoretic explanation is more illuminating (Bergvelt & ten Kroode, 1988). The 2×2 matrix in the AKNS scattering problem depends on a (spectral) parameter and so belongs to the loop algebra $\mathfrak{sl}_2$. There is a representation of the affine extension $\widehat{\mathfrak{sl}}_2$ in which the Heisenberg subalgebra, mentioned above, has infinitely many vacuum vectors killed by the a_k^* . The vacuum expectation values are the Toda τ -functions τ_n , and the AKNS variables are determined by $q_n = -\tau_{n+1}/\tau_n$, $r_n = \tau_{n-1}/\tau_n$.

The Two-dimensional Toda Lattice

The Toda-AKNS family has a sweeping generalization related to the Kadomtsev–Petviashvili equation (KP). It consists of four Lax equations which involve two infinite families of time variables, t_k, x_k . A continuum limit of this system was encountered in the study of deformations of a two-dimensional oil–water interface (Hele–Shaw flow) and has revealed an integrable structure of conformal mappings. This is sketched in the next section.

The operator $\mathbf{L}$ in (12) is replaced by a formal series, and a second operator $\mathbf{M}$ is introduced:

$$\mathbf{L} = \Delta + u_0 + u_1 \Delta^{-1} + u_2 \Delta^{-2} + \cdots, \quad (19)$$

$$\mathbf{M} = \Delta^{-1} + v_0 + \Delta v_1 + \Delta v_2 + \cdots. \quad (20)$$

The u_k, v_k are infinite diagonal matrices. Two of the Lax equations are

$$\begin{aligned} \frac{\partial \mathbf{L}}{\partial t_k} &= [\mathbf{B}_k, \mathbf{L}], \quad \mathbf{B}_k = (\mathbf{L}^k)_{+}, \\ \frac{\partial \mathbf{L}}{\partial x_k} &= [\mathbf{C}_k, \mathbf{L}], \quad \mathbf{C}_k = (\mathbf{M}^k)_{-}. \end{aligned} \quad (21)$$

The subscripts $\pm$ denote projections on the positive/negative powers of Δ (analog of upper/lower triangular). In the other two equations, $\mathbf{L}$ is replaced by $\mathbf{M}$ (Ueno & Takasaki, 1984).

Equations (21) specialize to the usual Toda lattice, the equations $\mathbf{L} = [\mathbf{B}, \mathbf{L}]$ for banded matrices $\mathbf{L}$, and an extension of the Toda lattice in which the q_n depend on two variables. This is the “two-dimensional Toda lattice” (2DTL).

The 2DTL is obtained as follows. The compatibility conditions of the two systems in (21) are “zero curvature equations.” With the abbreviations $x_1 = x$, $t_1 = t$,

the first of these is

$$\frac{\partial \mathbf{B}}{\partial x} - \frac{\partial \mathbf{C}}{\partial t} + [\mathbf{B}, \mathbf{C}] = 0. \quad (22)$$

Following the one-dimensional case (12), let $\mathbf{B} = -\Delta^{-1}a$ and $\mathbf{C} = b + \Delta$. a_n, b_n , still given by (11), are now functions of t and x . (22) becomes

$$(a_n)_x = a_n(b_{n+1} - b_n), \quad (b_n)_t = a_n - a_{n-1}$$

or

$$(q_n)_{xt} = \exp(q_{n-1} - q_n) - \exp(q_n - q_{n+1}). \quad (23)$$

A standard change of variables converts $(q_n)_{xt}$ to the wave operator $(q_n)_{\xi\xi} - (q_n)_{\tau\tau}$.

The free and periodic boundary conditions on the 2DTL are of primary interest. The free boundary condition for 2×2 matrices $\mathbf{B}, \mathbf{C}$ yields the Liouville equation

$$q_{xt} + \exp q = 0. \quad (24)$$

Under the periodic boundary condition $q_0 = q_2, q_1 = q_3$, system (23) becomes the sinh-Gordon equation for $\Theta = q_2 - q_1$,

$$\Theta_{xt} = -4 \sinh \Theta,$$

or, if q_1, q_2 are taken to be imaginary, the sine-Gordon equation

$$\Theta_{xt} = -4 \sin \Theta.$$

Since the sine-Gordon equation is solved by the inverse scattering method, it is natural to introduce a spectral parameter ζ and an eigenvalue problem for the N -component free 2DTL:

$$\Psi_t = \mathbf{B}(\zeta)\Psi, \quad \Psi_x = \mathbf{C}(\zeta)\Psi. \quad (25)$$

Sine-Gordon theory, in which ζ^{-1} appears, further suggests that for the free 2DTL

$$\mathbf{B}(\zeta) = -\zeta^{-1}\Delta^{-1}a, \quad \mathbf{C}(\zeta) = b + \zeta\Delta. \quad (26)$$

Compatibility of the two equations in (25) implies (22). The free 2DTL is referred to as ‘‘Toda field theory.’’

Periodic boundary conditions are handled by an adaptation of (26). ζ is put in the lower left corner of $\mathbf{B}(\zeta)$ and $-\zeta^{-1}a_N$ in the upper right corner of $\mathbf{B}(\zeta)$. The inverse scattering method can be applied to (25). Indeed, under two-periodic boundary condition, (25) is precisely the AKNS system used to solve the sine-Gordon equation.

The periodic 2DTL is called ‘‘affine Toda field theory’’ (ATFT), because, as is the case for the one-dimensional periodic lattice, it is set in the context of loop and affine Lie algebras and groups. The structure of ATFT, however, is richer because of the new x -dependence.

In complex coordinates $t = w, x = \bar{w}$, ATFT is a system of elliptic partial differential equations which is

encountered in the theory of harmonic maps. Solutions of the sinh-Gordon equation define Riemannian metrics on surfaces $z = f(x, y)$, $(x, y) \in U$, of constant mean curvature 2. The Gauss map, which sends the unit normal vector to the unit sphere S^2 , is a harmonic map, meaning that it is a critical point of the ‘‘energy’’ $\frac{1}{2} \int_U \|\nabla \phi\|^2 dx dy$ of maps $\phi : U \rightarrow S^2$. (For real-valued maps, a critical ϕ is an ordinary harmonic function.) Solutions of the multi-component elliptic ATFT define harmonic maps into other symmetric spaces. A certain group of loops is the infinite-dimensional symmetry group of this 2DTL: given a solution of 2DTL and a loop, one can construct a new solution via a factorization problem (Guest, 1997; Fordy & Woods, 1994).

In wave equation form, $(q_n)_{\xi\xi} - (q_n)_{\tau\tau}$, the 2DTL equations are hyperbolic; they describe fields on two-dimensional Minkowski space. As a first step toward a quantum theory of these fields, one can ask whether they are conformally invariant. Conformal transformations scale the (indefinite) metric. In light cone coordinates $x_{\pm} = \xi \pm \tau$, they are given by $(x_+, x_-) \mapsto (f_+(x_+), f_-(x_-)) = (\bar{x}_+, \bar{x}_-)$. Then $(q_n)_{x_+x_-}$, the left side of (23), becomes

$$\frac{\partial x_+}{\partial \bar{x}_+} \frac{\partial x_-}{\partial \bar{x}_-} (q_n)_{\bar{x}_+\bar{x}_-}, \text{ abbreviated } J \cdot (q_n)_{\bar{x}_+\bar{x}_-}. \quad (27)$$

The 2DTL equations will be conformally invariant under a transformation of the fields, $q_n(x_{\pm}) \mapsto \bar{q}_n(\bar{x}_{\pm})$, for which the right-hand side of (23) is also multiplied by J .

The Liouville equation (24) is conformally invariant if q transforms according to $q \mapsto \bar{q} + \ln J$. The sinh-Gordon equation, whose right side is $-2(\exp(\Theta) + \exp(-\Theta))$, admits no such transformation of Θ and is not conformally invariant. A particle described by sinh-Gordon theory has ‘‘mass’’: if $\sinh \Theta$ is linearized about the vacuum state $\Theta = 0$, one obtains $\Theta_{x_+x_-} = -4\epsilon$; the mass is $\sqrt{4}$. The sinh-Gordon equation is a perturbation of the conformal Liouville field equation. For example, under the change of variables $q \mapsto \Theta + \ln \epsilon$, the equation

$$q_{x_+x_-} = -e^q + \epsilon^2 e^{-q},$$

becomes the sinh-Gordon equation with mass $\sqrt{2}\epsilon$. As $\epsilon \rightarrow 0$, which recovers the Liouville equation, the mass tends to zero. Similarly, Toda field theory is conformally invariant, while affine Toda field theory is not. Affine Toda field theory is massive in the sense described. The actual fields of interest are linear combinations of the q_n that are suitable for generalization to affine Lie algebras. This generalization is important, because the quantizations of ATFTs associated to different types of affine Lie algebras can have very different properties (Corrigan, 1999).

Continuum Limits

There are two natural continuum limits of the Toda mass-spring chain. Keeping both nonlinearity and dispersion to first order, one gets the KdV equation. The “zero dispersion limit” results in a hyperbolic system, called the “dispersionless Toda lattice.”

The approximation leading to the KdV equation is taken in a right-moving coordinate system, so that the left-moving solitons of the Toda lattice disappear. The difference operator (6) becomes the Schrödinger operator, and the discrete Gel'fand-Levitan-Marchenko inverse theory limits to the inverse scattering formalism for KdV (Toda, 1981).

The zero dispersion limit retains only the quadratic nonlinearity. In the Toda equations $\dot{a}_n = a_n(b_n - b_{n+1})$, $\dot{b}_n = 2(a_{n-1}^2 - a_n^2)$, take $q = n\varepsilon$ and $T = t\varepsilon$. These are slow scales. With $b_n(T) \sim b(q, T)$, the difference $(b_n - b_{n+1})$ is approximately $-\varepsilon b_q$. The inconvenient minus signs are removed by redefining a_n, b_n . One then finds the DTL equations

$$a_T = ab_q, \quad b_T = 2(a^2)_q. \quad (28)$$

There are again Lax equations. In the Toda eigenvalue problem (6), write $\exp(\pm \varepsilon \partial / \partial n)$ for the shift by $\pm \varepsilon$, and assume a WKB ansatz for $y_n(T) \sim y(q, T)$,

$$y(q, T) = \exp[\varepsilon^{-1} S(q, T)].$$

In the WKB approximation to the Schrödinger wave function, S_q is the inverse wavelength, which is proportional to momentum, by the deBroglie relation. Set $p = S_q$. Thus, p and q are canonically conjugate variables. As $\varepsilon \rightarrow 0$, the eigenvalue problem $\mathbf{L}y = \lambda y$ reduces to an eikonal equation, and $\mathbf{y}_T = \mathbf{B}\mathbf{y}$ becomes the time-evolution of the momentum S_q :

$$\begin{aligned} \mathcal{L}(p, q) &:= a(e^p + e^{-p}) + b = \lambda, \\ p_T &= \frac{\partial}{\partial q} [a(e^p - e^{-p})] := \frac{\partial}{\partial q} \mathfrak{B}(p, q). \end{aligned} \quad (29)$$

The commutator $[\mathbf{L}, \mathbf{B}]$ is replaced by the Poisson bracket with respect to p and q , and then

$$\dot{\mathcal{L}} = \{\mathfrak{B}, \mathcal{L}\}$$

yields Equations (28). Their solutions may develop shocks, but as long as they are smooth, the dispersionless limits of the Toda lattice constants of motion, I_k , are constants of motion, say H_k , for (28). For example, $\sum (2a_n^2 + b_n^2) \rightarrow H_2(a, b) = \int (2a^2 + b^2) dq$.

For smooth solutions, the eigenvalue sorting property of the free Toda lattice remains valid. The “free” boundary conditions are $a(q, T) = 0$ for $q = 0, q = 1$. Let $a_0(q), b_0(q)$ be the initial values. As $T \rightarrow \infty$, $a(q, T) \rightarrow 0$, while $b(q, T)$ tends to a decreasing function $b^*(q)$. The conserved quantities H_k have the same values for b^* as for a_0, b_0 , for

example, $H_2(a_0, b_0) = H_2(0, b^*)$. In this sense, the initial “matrix” a_0, b_0 becomes diagonal, and the “eigenvalues” are sorted (Brockett & Bloch, 1990).

The two-dimensional dispersionless Toda lattice hierarchy arises in an idealized model of viscous fingering in a Hele-Shaw cell. This sketch follows Kostov et al. 2001 and references therein. Two plates confine water (zero viscosity) and oil (viscous) in the complex z -plane. The water occupies a bounded region D_+ , which is surrounded by oil in the exterior domain D_- . There is a source of water at $z = 0$ and a compensating sink for the oil at $z = \infty$. The object is to find the motion of the interface $\Gamma(t)$. Under some simplifying assumptions, the time development of Γ is governed by the “Laplacean growth equation” (LGE), so called because the velocity potential satisfies $\Delta \phi = 0$.

The shape of Γ is determined by the harmonic moments

$$\begin{aligned} t_k &= -\frac{1}{k\pi} \int_{D_-} z^{-k} dx dy, \quad k \geq 1, \\ t_0 &= \frac{1}{\pi} \times \text{area of } D_+. \end{aligned} \quad (30)$$

It is known that the t_k are constant under the LGE, while the area t_0 changes linearly. One, therefore, takes t_0 as time variable. Finding $\Gamma(t_0)$ amounts to finding the time-dependent conformal map $\mathcal{L}(t_0)$ from $\{w \mid |w| > 1\}$ to $\{z \mid z \in D_-\}$. The dispersionless limit of the two-dimensional Toda hierarchy (21) enters when one allows the moments $\mathbf{t} = (t_1, \dots)$ to vary and considers a family $\mathcal{L}(t_0, \mathbf{t})$ of conformal maps; the LGE is then recovered as a constraint on this family.

The time-like variables t_k, x_k in (21) are taken to be the moments t_k and their conjugates $\bar{t}_k$. The area t_0 plays the role of the spatial coordinate q in (28); also set $w = \exp p$. The conformal map $\mathcal{L}(w, \mathbf{t})$ and its conjugate $\bar{\mathcal{L}}(w^{-1}, \bar{\mathbf{t}})$ are the dispersionless limits of $\mathbf{L}$ and $\mathbf{M}$. The expansion of $\mathbf{L}$ in powers of Δ^{-1} becomes the Laurent expansion $\mathcal{L}(w) = \text{const} \cdot w + u_0 + u_1 w^{-1} + \dots$. The dependence of $\mathcal{L}, \bar{\mathcal{L}}$ on the deformation parameters $\mathbf{t}, \bar{\mathbf{t}}$ is given by

$$\frac{\partial \mathcal{L}}{\partial t_k} = \{\mathfrak{B}_k, \mathcal{L}\}, \quad \frac{\partial \bar{\mathcal{L}}}{\partial \bar{t}_k} = -\{\bar{\mathfrak{B}}_k, \bar{\mathcal{L}}\}, \quad (31)$$

plus similar equations for $\bar{\mathcal{L}}$. As in (21), $\mathfrak{B}_k$ is $(\mathcal{L}^k)_+$. The Poisson bracket is still $\{p, q\} = 1$ or in the new notation, $\{\ln w, t_0\} = 1$. The Laplacean growth equation can be written in the form

$$\{\mathcal{L}(w, t_0), \bar{\mathcal{L}}(w^{-1}, t_0)\} = 1,$$

with all $t_k, \bar{t}_k$ fixed. The constraint $\{\cdot, \cdot\} = 1$ is known as the “dispersionless string equation.”

Other Topics

The topics chosen give only a hint of the importance of the Toda lattice and its generalizations. Other aspects and applications that deserve an expanded description include the following.

The Toda mass-spring chain can model dispersive lattice shocks. Two unstretched halves of the lattice move toward each other at constant speed $2c$. In the scattering problem, the boundary condition is not $b_{|n|} \rightarrow 0$, but $b_n \rightarrow \mp c$ for $n \geq 0$. The spectrum changes with c , and this is reflected in the shockwave behavior, which is analyzed by means of the powerful steepest descent method for Riemann–Hilbert problems (Deift et al., 1995).

The quantized Toda lattice is solvable; the eigenstates of the multi-particle Toda Hamiltonian are matrix elements of infinite-dimensional group representations. The construction generalizes the one-dimensional case, $-\mathrm{d}^2/\mathrm{d}q^2 + \exp(-2q)$, whose eigenfunctions are Whittaker functions (Semenov-Tyan-Shansky, 1994a).

Orthogonal polynomials satisfy a three-term recurrence relation such as (6). For this reason, the Toda lattice arises in random matrix theory. A probability measure

$$\mathrm{d}\mu_N(H) = Z_N^{-1} \mathrm{e}^{-N\mathrm{Trace}V(H)} \mathrm{d}H$$

on Hermitean matrices is given. It determines a family $p_j(x)$ of orthogonal monic polynomials, $\int p_i(x)p_j(x)\mathrm{d}\mu_N(x) = 0$ if $i \neq j$. In this basis, the shift operator $Lp(x) = xp(x)$ acting on polynomials $p(x)$ has the Jacobi form (12). If $V(x)$ depends on parameters t_k , for example, $V(x) = x^2 + t_4x^4$, then $\mathrm{d}\mu_N$ and the p_j depend on the t_k . The change of L in the moving basis $\{p_j\}$ is described by a Lax equation (Witten, 1991).

TOPOLOGICAL DEFECTS

A *topological defect* (or *topological soliton*) represents a spatially non-uniform configuration of an order parameter field that offers topological stability and cannot be transformed into the ground state of a system under finite deformation of a field (Mermin, 1979). The structure and properties of a topological defect (TD) depend essentially on the dimensionality of a system, its symmetry, and degeneration of the ground state. Historically, vortices in liquid were the first example of a TD to be investigated (Lugt, 1996). In a two-dimensional (2-d) incompressible liquid, the equation

$\Delta\varphi = 0$ for the velocity potential φ (velocity $\mathbf{v} = \nabla\varphi$) has the evident solution $\varphi = \kappa\chi$ for the vortex, where κ is an arbitrary parameter and χ is the azimuthal angle in cylindrical coordinates (ρ, χ) in the x, y plane with its origin in the vortex center.

Pitaevskii vortices in superfluidity theory (Lifshitz & Pitaevskii, 1980), *magnetic vortices* in easy-plane ferro- and anti-ferromagnets (FMs and AFMS) (Mertens & Bishop, 2000), magnetic *disclinations*, and disclinations in nematic liquid crystals (de Gennes, 1974) exemplify the similar one-dimensional TD in 3-d continuous media with continuous degeneration of the ground state. The order parameters in the above examples are of the two-component type: the complex thermodynamical wave function $\psi(\mathbf{r}, t) = \psi_0 \exp(i\phi)$ of a Bose condensate for the superfluid liquid, which, within the approach of a weakly nonideal Bose gas, satisfies the Gross–Pitaevskii equation

$$i\hbar \frac{\partial \psi}{\partial t} + \frac{\hbar^2}{2m} \Delta \psi + U\{\psi - |\psi|^2 \psi\} = 0, \quad (1)$$

and two angle variables (θ, ϕ) in polar coordinates in magnetic space (associated with the hard axis z) of a magnetization vector $\mathbf{M} = M_0(\sin\theta \cos\phi, \sin\theta \sin\phi, \cos\theta)$, which satisfies the Landau–Lifshitz equation (similar in structure to (1)), or the director vector $\mathbf{L}$ in antiferromagnets and liquid crystals. These parameters are continuously degenerate in the phase of wave function ψ or in the direction of spins (or elongated molecules), defined by the angle ϕ in the easy-plane.

The solutions for the discussed TD map a plane (x, y) , perpendicular to the defect line in coordinate space, onto the 2-d manifold of the order parameter (complex plane of ψ , half-sphere of radius $|\mathbf{M}|$, or sphere of radius $|\mathbf{L}|$). For example, the solution of (1) has the form $\psi = \psi_0(\rho) \exp(in\chi)$, where $n = \pm 1, \pm 2, \dots$ and $(\pm)$ correspond to the vortex and antivortex. The density of a Bose gas tends to zero in the center of the vortex, $\psi^2(0) = 0$, and the solution has no singularity. A magnetic vortex has the same properties: $\phi = n\chi$ ($n = \pm 1, \pm 2, \dots$), $\theta(\rho = 0) = 0$ or π , $\theta(\rho \rightarrow \infty) \rightarrow \pi/2$ (Kosevich et al., 1990). In AFM- and nematic disclinations $\phi = k\chi/2$, where $k = \pm 1, \pm 2, \dots$, is called the Frank index. The mapping degree of TD is usually characterized by some integral *topological invariant* (or *topological charge*) related to the solution under consideration. The hydrodynamic vortex in an incompressible liquid is defined by its total vorticity $(1/2\pi) \oint \mathbf{v} d\mathbf{l}$, where integration is performed over the contour enclosing the vortex center. This value coincides with κ and can be arbitrary. Other types of vortices can be characterized by the same integral $\oint \nabla\phi d\mathbf{l}$. (Since a contour can be chosen with an infinite radius, these topological solitons are nonlocalizable.) But in some cases, the topological charge is more conveniently defined as the 2-d integral over the coordinate plane. For example, in

a ferromagnet, this invariant is

$$Q = \frac{1}{4\pi} \int m \left(\frac{\partial m}{\partial x_\alpha} \times \frac{\partial m}{\partial x_\beta} \right) \varepsilon_{\alpha\beta} d^2x \\ = \frac{1}{2\pi} \int \sin\theta d\theta d\phi, \quad (2)$$

where $m = M/M_0$. For a magnetic vortex $Q = pn$, where $p = m_z(\rho = 0)$, is the polarity of the vortex.

Another situation appears in systems with discrete degeneracy of the ground state. For instance, a localized magnetic 2-d topological soliton (TS) (*magnetic skyrmion*) of the type $\phi = n\chi$, $\theta = \theta(\rho)$, and $\theta(0) = 0$, $\theta(\infty) = \pi$ can exist in the easy-axis ferromagnet with two equivalent ground states $m_z = \pm 1$. At fixed n , the topological charge for this skyrmion is twice that for the vortex. Moreover, in such a system, TDs can exist in the 1-d and 3-d cases. In 3-d easy-axis FM, the TS, localized in all 3 dimensions, corresponds to the solution with the nonzero integer Hopf invariant. The 1-d TS can exist in 1-d and quasi-1-d systems or in 2-d and 3-d media as solutions depending on one spatial coordinate. Such a TD describes the *domain wall* in ferromagnets. In the framework of the Landau–Lifshitz equation, the corresponding *kink* solution is written as

$$\theta(x) = \arccos(\tanh(x/l_0)), \quad \phi = \text{const.}, \quad (3)$$

where l_0 is the magnetic length. The domain boundary (kink) separates two half-spaces in different ground states. The topological charge, analogous to (2), can be defined in this case as follows: $Q = (1/2\pi) \int \sin\theta(x) d\theta(x) d\phi(x)$. If an additional anisotropy in the plane perpendicular to the easy axis is taken into account (in orthorhombic ferromagnets), more complicated TDs can exist inside the domain walls: *Bloch lines* and *Bloch points*. Similar to (3), the kink-like TD can exist in other systems with discrete degenerate ground states: kinks in antiferromagnets, kinks of incommensurate surface structures, fluxons in a long Josephson junction, phase boundaries in the problem of structural phase transitions, solitons in polyacetylene, in 1-d metals in the Peierls–Fröhlich phase, and so on. Usually these TDs are investigated within the framework of the ϕ^4 -model or sine-Gordon equation

$$\frac{\partial^2 w}{\partial t^2} - s^2 \frac{\partial^2 w}{\partial x^2} + \omega_0^2 \sin w = 0, \quad (4)$$

where the field variable w and coefficients have different physical meanings for various systems. The topological solution to this equation is well known: $w = 4 \arctan \exp((x - vt)/l\sqrt{1 - v^2/s^2})$ with $l = s/\omega_0$.

A crystal *dislocation* represents one of the most important examples of a TD in a crystal lattice. Dislocations exist due to the translational symmetry

of the lattice: it transforms into itself under the translation by the interatomic distance a . (Rotational symmetry of the crystal lattice leads to the existence of another TD—crystal *disclination*.) A dislocation represents a one-dimensional TD with the following properties: the regular lattice structure is distorted only in the core of the dislocation line and the total displacement, as a closed contour goes around the dislocation line, is equal to the translation period. (In two-sublattice antiferromagnets, this translation period is twice as small as that for a magnetic lattice.) This fact leads to the appearance of the magnetic disclination and formation of the complex magnet-structural TD (Kovalev & Kosevich, 1977). In the simplest case of a screw dislocation or in a scalar model, the deformation is characterized solely by one component of displacement, u . Then, within the elasticity theory approximation, the deformation of a crystal is governed by the equation $\Delta u = 0$ with the dislocation solution $u = a\chi/2\pi$. (Here, a plays the role of the topological charge of the dislocation: $\oint du = a$.) The above solution is singular and does not describe the discrete structure of the dislocation core. It can be investigated in the simple one-dimensional model proposed by Yakov Frenkel and Tatiana Kontorova (1938) (See also **Frenkel-Kontorova model**). The FK model was the first 1-d model for 2-d topological defects. Within this model, the relative displacements u of the atoms from two atomic rows above and below the dislocation center are described by Equation (4), where $w = 2\pi u/a$, $\omega_0 = (2\pi/a)\sqrt{U/m}$, m is the atomic mass, s is the velocity of sound, U is the energy of the interaction between the rows, and l is the width of the dislocation core. The energy of a stationary dislocation (kink) is $E_0 = (4/\pi)\sqrt{ms^2U}$. The integral $\int \partial u/\partial x dx$ now plays the role of the topological charge. The FK model describes more adequately other TDs in the crystal lattice: *crowdions*, kinks of incommensurate surface structures, and dislocation kinks.

The dynamics of TDs are of great variety and depend strongly on the nature of the TD. The dynamics of dislocations, dislocation kinks, crowdions, domain walls, and phase boundaries are very simple within the framework of the Lorentz-invariant 1-d FK model: the kink can move with velocities below the velocity of sound in a system and its effective mass can be considerably smaller than the atomic mass. Actually, the dynamics of TDs in a lattice is much more complicated. Dislocations move mainly in some preferred direction (in slip planes), and crowdions propagate in closely packed atomic rows in a “relay race” manner. The discreteness of a lattice gives rise to Peierls relief for TP, and its dynamics assume diffusive features. Dislocation creeps over this relief, producing the dislocation kinks. The dynamics of vortices in media with distributed parameters has some interesting peculiarities. An isolated vortex in an infinite ideal

medium cannot move: it is frozen in a liquid or superfluid flow or spin flux. The vortex can move in a bounded area or in the presence of other defects but these dynamics are non-Newtonian. Within the collective coordinates approach, the effective equation of motion for the center of a vortex $X(t)$ is (Thiele, 1973)

$$\frac{dX}{dt} \times G = F_G, \quad (5)$$

where the force F_G is formally equivalent to the Magnus force in fluid dynamics and the gyrocoupling vector G is parallel to the line of a vortex and depends on its topological charge.

In all the examples above, topological defects with the opposite sign of the topological charge exist (vortex-antivortex, kink-antikink, dislocations with opposite signs, etc). This implies that TDs can emerge from the ground state of a medium in pairs with zero total topological charge. At a nonzero temperature, these pairs dissociate and the finite density of TDs can be observed. Seeger & Schiller (1966) were the first to develop the thermodynamics of topological solitons in the framework of the 1-d FK model. As they showed, the equilibrium density of kinks and antikinks at a temperature T is

$$n \approx \frac{a}{l} \sqrt{\frac{2}{\pi\tau}} \exp\left(-\frac{1}{\tau}\right), \quad (6)$$

where $\tau = k_B/E_0$, E_0 is the soliton energy, and l is the width of this kink. The situation with a TD in the 2-d case (vortices and 2-d dislocations) is essentially different. The energy of vortices and dislocations in infinite 2-d systems is infinite, but in systems of size R , it is of the order of $E_v \sim E_* \ln(R/a)$, where E_* is a characteristic energy, being specific for different TDs. The contribution from a vortex or dislocation to configuration entropy in a 2-d crystal is $\delta S = \ln(R/a)^2$, and hence, the change in free energy, if one TD is added, is $\delta F = (E_* - 2T) \ln(R/a)$. At the temperature $T_c = E_*/2$, the value δF becomes negative and a Berezinskii–Kosterlitz–Thouless phase transition takes place: the crystal melts or magnetic ordering is broken (Berezinskii, 1971).

As indicated above, topological defects play an important role in the kinetic and thermodynamic properties of condensed matter. Dislocations and dislocation kinks cause plasticity and strengthening of a crystal, and their behavior under radiation depends to a large extent on the crowdions. Recently, the influence of dislocations on the concentration and mobility of current carriers has been widely studied experimentally in pure semiconductor and alkali-halide crystals (Osip’yan et al., 2000). Topological defects (charge-density-wave solitons) make an essential contribution to the conductivity and electrodynamics of

quasi-1-d conductors such as $(\text{CH})_x$, TaS_2 , and NbSe_2 (Krive et al., 1986).

TOPOLOGY

Continuity is conventionally associated with functions defined on the real line or higher-dimensional Euclidean spaces. Topology is concerned with the abstraction of continuity to maps between more

general sets. The subject is vast and its study can take many forms depending on the nature of the structures considered. They include the areas of point-set, combinatorial, algebraic, and differential topology.

A topological space has a distinguished collection of subsets known as *open sets*. An open subset U of the real line $\mathbb{R}$ is one for which every point of U is a subset of some real interval wholly contained in U . Thus, every point of U is the *interior* of U . Openness of a set U can also be expressed using the Euclidean distance, or *metric*, by saying that for every point $x \in U$, all points within a sufficiently small distance of x also lie in U . Thus, metrics can be used to create open sets. Complements of open sets are said to be *closed*. The simplest examples of open and closed sets in $\mathbb{R}$ are, respectively, the "open interval" (a, b) of all points between the numbers a and b excluding the end points, and the "closed interval" $[a, b] = (a, b) \cup \{a, b\}$. Also, sets can be neither open nor closed, for example $[a, b) = (a, b) \cup \{a\}$.

A *topology* on a set X is defined by its collection of open subsets, τ , which then makes X a *topological space* (X, τ) . The collection of open subsets must include both X and the empty set ϕ , any union of elements of τ , and the intersection of any finite collection of elements of τ . The conditions for a topology can equally well be cast in terms of closed sets. Also, a set can have many different topologies.

In any sophisticated mathematical structure, there is usually a way of relating two objects. For example, if we are only considering sets, say X and Y , we consider maps $f: X \rightarrow Y$. The natural equivalence for sets X, Y would be the existence of a map $f: X \rightarrow Y$ which is both one-one and onto, that is, a bijection. When topologies are placed on X and Y , it is natural to consider maps $f: X \rightarrow Y$ that are continuous. The metric definition of continuity for maps $f: \mathbb{R} \rightarrow \mathbb{R}$, or more generally $f: \mathbb{R}^m \rightarrow \mathbb{R}^n$, can be shown to be equivalent to the topological definition: $f: X \rightarrow Y$ is continuous if V is an open subset of Y ; the set $f^{-1}(V)$ is an open subset of X .

This alternative definition of continuity is the one that makes topology a key mathematical discipline of widespread importance.

The corresponding equivalence for topological spaces X and Y requires a map $h: X \rightarrow Y$, which is both (i) a bijection, and (ii) bicontinuous; that is, both h and its inverse h^{-1} are continuous. Such a map is called a *homeomorphism*. The spaces X and Y are said to be topologically equivalent or homeomorphs. Any subset S of a topological space X can be made into a topological space by declaring the intersections of open sets of X with S to be open sets of S . In fact, this collection of subsets of S forms a topology on S , called the *subspace topology*. Thus, important geometrical objects which are subsets of Euclidean spaces such as the circle, the sphere (and therefore all classical

polyhedra), the torus, the pretzel, and the Klein bottle (see Figure 1) can all be seen as topological spaces when endowed with the subspace topology.

An important property of continuous functions defined on the real numbers is that a continuous function defined on a bounded closed interval attains its bounds; that is, there exist points at which the function takes its maximum and minimum value. This is not true if the “closed, bounded” condition is relaxed. For example, $f(x) = x$ is not bounded on the real line $\mathbb{R}$ which is a closed (but not bounded) set. Also, $f(x) = x$ does not attain its bounds on the bounded (but not closed) set $(0, 1)$. The bounded closed interval on $\mathbb{R}$ is called a *compact set*. Again, such a set can be defined solely in terms of open sets, and so we can define the concept of a *compact topological space* (Munkres, 2000).

Another key result in elementary analysis is that the continuous image of an interval of real numbers is also an interval. This property is often used to find roots of a continuous function $f: \mathbb{R} \rightarrow \mathbb{R}$ by finding values $a, b \in \mathbb{R}$ for which $f(a) \cdot f(b) < 0$, the so-called “intermediate value” theorem. In the generalization of this result to topological spaces, the key property of the interval is its *connectedness*. The analogous result for topological spaces is that the continuous image of a connected set is also a connected set. The characterization of connectedness in the real numbers can be described purely in terms of the properties of the open sets on the real line, that is, in terms of the Euclidean topology on $\mathbb{R}$.

Thus, both compactness and connectedness are topological properties in the sense that they can be described purely in terms of properties of the open sets of a topological space (Munkres, 2000).

In some areas of topology, the importance of the open sets is not so apparent and other features of the topological space are considered. For example, polyhedra such as the cube, tetrahedron, and dodecahedron are finite ways of building homeomorphic images of the standard sphere. We note that for all such constructs, the number of vertices (V), edges (E), and faces (F) satisfy the condition $V - E + F = 2$, the *Euler characteristic* of the sphere. The torus, when built up in terms of faces, edges, and vertices, has the property that its Euler characteristic is zero. Given that the numbers V , E , and F are conserved by homeomorphism, we see that the torus and sphere having different Euler characteristics not only makes them look “different,” but ensures that they are not homeomorphic; that is, they are topologically distinct.

Note that not all spaces can be easily distinguished using topology. For example, the subsets of rational numbers, $\mathbb{Q}$, and the irrationals, I , of the real line $\mathbb{R}$, are both topologically *dense* sets in $\mathbb{R}$; that is, for both sets, the smallest closed superset is the whole interval $\mathbb{R}$. Also, both are neither open nor closed. However, note that there is no bijection between the sets $\mathbb{Q}$ and

Figure 1. Four distinct topological spaces: (a) sphere; (b) torus; (c) cylinder; (d) Möbius band. See <http://library.wolfram.com/graphics/>

I because they have different cardinalities and, thus, cannot be homeomorphs.

The topological spaces mentioned above, such as the torus, sphere, and pretzel, can be easily visualized within the three-dimensional Euclidean space $\mathbb{R}^3$ in which we locally live. However, it is not difficult to see how we can start to construct spaces in $\mathbb{R}^3$ which are more geometrically demanding. The simplest is the Möbius strip, M , which is derived from the rectangle by pasting together one opposite pair of edges of a band with a half-twist, see Figure 1(d). Note that the Möbius band has only one “side”; just draw a pen line along the spine of the band and the line arrives on the opposite side of the paper from its initial point. Continuing the

line brings a return to the initial point of the curve. By comparison, one cannot get from one side of a cylinder to the other without passing across one of its edges. The Möbius band is topologically different from the cylinder for several reasons. For instance, the boundary of the cylinder consists of two disjoint circles whereas that of the Möbius band is a single circle.

TRAFFIC FLOW

Most automobile drivers have encountered the widespread phenomenon of so-called “phantom traffic jams,” for which there is no visible reason such as an accident or a bottleneck. Why are vehicles sometimes stopped although everyone likes to drive fast? Due to the finite adaptation time (= reaction time + acceleration time), a small disturbance in the traffic flow Q_* can cause an overreaction (overbraking) of a driver, if the safe vehicle speed $V_*(\rho)$ drops too rapidly with increasing vehicle density ρ . At high enough densities ρ , this will give rise to a chain reaction of the followers, as other vehicles will have approached before the original speed can be regained. This feedback can eventually cause the unexpected standstill of vehicles known as traffic jam.

Lighthill & Whitham (1955) described traffic flow as a function of space x and time t by means of a fluid-dynamic conservation law of vehicles, reflecting the fact that vehicles are not generated or lost in the absence of ramps, intersections, or accidents. The traffic flow $Q(x, t)$ (= vehicle density $\rho(x, t) \times$ average velocity $V(x, t)$) was specified as a function of the density $\rho(x, t)$. The corresponding “fundamental diagram” $Q_*(\rho) = \rho V_*(\rho)$ is obtained as a fit to experimental data. The conservation law $\partial \rho / \partial t + \partial Q / \partial x = 0$ leads to the nonlinear wave equation

$$\frac{\partial \rho}{\partial t} + C(\rho) \frac{\partial \rho}{\partial x} = 0, \quad (1)$$

according to which the propagation velocity

$$C(\rho) = V_*(\rho) + \rho \frac{dV_*(\rho)}{d\rho} \leq V_*(\rho) \quad (2)$$

of kinematic waves depends on the vehicle density. Thus, while a density profile on a ring road keeps its amplitude, its shape is changing until shock waves (i.e., discontinuous changes in the density) have developed. The densities ρ_+ and ρ_- immediately upstream and downstream of a shock front determine its propagation speed

$$S(\rho_+, \rho_-) = \frac{Q_*(\rho_+) - Q_*(\rho_-)}{\rho_+ - \rho_-}. \quad (3)$$

As discontinuous density changes are not fully consistent with empirical observations and a problem for efficient numerical integration, Whitham (1974) has suggested adding a diffusion term $D \partial^2 \rho / \partial x^2$ with $D > 0$ to the right-hand side of the Lighthill–Whitham equation. For the linear velocity-density relation $V_*(\rho)$ suggested by Greenshields (1935), the resulting equation is equivalent with the Burgers equation and can be transformed into the linear heat or diffusion equation; that is, it is analytically solvable.

Experimental observations of traffic patterns show some additional features that cannot be reproduced by the above models. While traffic flow appears to be stable with respect to perturbations at small and large densities, there is a linearly unstable range at medium densities, where already small disturbances of uniform traffic flow give rise to traffic jams. Between these three density ranges, one finds meta- or multistable ranges, since there exists a density-dependent, critical amplitude $A(\rho)$, so that the resulting traffic pattern is path- or history-dependent (Kerner et al., 1994–1997). While subcritical perturbations fade away, supercritical perturbations cause a breakdown of traffic flow (nucleation effect). Consequently, traffic flows display critical points, nonequilibrium phase transitions, noise-induced transitions, and fluctuation-induced ordering phenomena.

One may view this situation as nonequilibrium analogue of the phase transitions between vapor, water, and ice. However, the breakdown and structure formation phenomena, when the “temperature” (i.e., the fluctuation strength) is increased, are sometimes counterintuitive due to the repulsive nature of vehicular interactions. From classical many-particle systems with attractive interactions, we are rather used to the idea that increasing temperature breaks up structures and destroys patterns (fluid structures are replaced by gaseous ones, not by solid ones).

The above observations in freeway traffic can be described by microscopic, mesoscopic, or macroscopic models, which are theoretically connected by means of a micro-macro link. Microscopic models are usually

follow-the-leader models specifying the acceleration dv_i/dt of the single vehicles i as a function of their distance headway $d_i = x_{i-1} - x_i$, their speed v_i , and/or their relative velocity $\Delta v_i = v_i - v_{i-1}$:

$$\frac{dv_i}{dt} = f(d_i, v_i, \Delta v_i). \quad (4)$$

A typical example is the non-integer car-following model:

$$\frac{dv_i(t + \Delta t)}{dt} = -\frac{\Delta v_i(t)}{T} \frac{[v_i(t + \Delta t)]^m}{[d_i(t)]^l} \quad (5)$$

with the reaction time $\Delta t \approx 1.3$ s and the parameters $T \approx \Delta t/0.55$, $m \approx 0.8$, and $l \approx 2.8$ (Gazis et al., 1961). It has a linearly unstable range for $\Delta t/T > \frac{1}{2}$. A simpler model is the optimal velocity model

$$\frac{dv_i(t)}{dt} = \frac{1}{\tau} [v(d_i(t)) - v_i(t)], \quad (6)$$

where $v(d_i)$ is the “optimal” velocity-distance relation and τ the adaptation time (Bando et al., 1994, 1995). This model has an unstable range for $dv(d_i)/dd_i > 1/(2\tau)$. The respective nonlinearly coupled differential equations (or stochastic differential equations, if fluctuations are taken into account) are numerically solved as in molecular dynamics. An alternative approach is rule-based cellular automata, which discretize space and time in favor of numerical efficiency: $t = i\Delta t$, $x = j\Delta x$, $d = \hat{d}\Delta x$, $v = \hat{v}\Delta x/\Delta t$. The Nagel-Schreckenberg model (1992), for example, can be written in the form

$$\hat{v}_{i+1} = \max \left(0, \min(\hat{v}_{\max}, \hat{d}_i - 1, \hat{v}_i + 1) - \xi_i^{(p)} \right), \quad (7)$$

where $\hat{v}_{\max}\Delta x/\Delta t$ is the maximum velocity and $\xi_i^{(p)}$ a Boolean random variable which is 1 with probability p and 0 otherwise. Typical parameters are $\Delta t = 1$ s, $\Delta x = 7.5$ m, $\hat{v}_{\max} = 5$, and $0.2 < p \leq 0.5$.

Mesoscopic models describe the spatiotemporal change of the phase space density (= vehicle density $\times$ velocity distribution). This approach has been introduced by Prigogine et al. (1960, 1961, 1971) and is inspired by kinetic gas theory. The related equations are either of Boltzmann type (for point-like vehicles or low densities) or of Enskog type, if vehicular space requirements at moderate and high densities are taken into account (Helbing et al., 1995–1999). The equations allow a systematic derivation of a hierarchy of macroscopic equations for the vehicle density $\rho(x, t)$, the average velocity $V(x, t)$, the velocity variance $\Theta(x)$, etc. This hierarchy is usually closed after the velocity or variance equation, although the separation of time scales assumed by the underlying approximations is weak. Nevertheless, the observed

traffic dynamics are rather well reproduced by the resulting coupled partial differential equations. The density equation is just the continuity equation

$$\frac{\partial \rho}{\partial t} + \frac{\partial(\rho V)}{\partial x} = v_+ - v_-, \quad (8)$$

where v_+ and v_- denote on- and off-ramp flows, respectively. The velocity equation can be cast into the form

$$\frac{\partial V}{\partial t} + V \frac{\partial V}{\partial x} = -\frac{1}{\rho} \frac{\partial P}{\partial x} + \frac{1}{\tau} (V^* - V). \quad (9)$$

In theoretically consistent macroscopic traffic models such as the gas-kinetic-based traffic model, the “traffic pressure” P and the velocity V^* are nonlocal functions of the density ρ , the average velocity V , and the variance Θ (Helbing et al., 1998, 1999). The Lighthill–Whitham model (1955) results in the unrealistic limit $\tau \rightarrow 0$ of vanishing adaptation times τ . Payne’s macroscopic traffic model (1971, 1979) is obtained for $P(\rho) = [V_0 - V_*(\rho)]/(2\tau)$ and $V^* = V_*(\rho)$, where V_0 denotes the (average) desired velocity (the average velocity at very low densities). Kerner and Konhäuser’s model (1993) is a variant of Kühne’s model (1984) and corresponds to the specifications $P = \rho\Theta_0 - \eta_0\partial V/\partial x$, and $V^* = V_*(\rho)$, where Θ_0 and η_0 are positive constants. The corresponding equation is a Navier–Stokes equation with a viscosity term $\eta_0\partial^2 V/\partial x^2$ and an additional relaxation term $[V_*(\rho) - V]/\tau$ describing the delayed adaptation to the velocity–density relation $V_*(\rho)$. The condition for linear instability reads

$$\rho \left| \frac{dV_*(\rho)}{d\rho} \right| > \sqrt{\frac{dP(\rho)}{d\rho}}; \quad (10)$$

that is, the Payne model and the Kerner–Konhäuser model have linearly unstable ranges, if $dV_*(\rho)/d\rho$ is large, while the Lighthill–Whitham model is marginally stable. The Burgers equation, by the way, is always stable.

According to Krauß (1998), traffic models show the observed hysteretic phase transition related with metastable traffic and high flows only, if the typical maximal acceleration is not too large and the deceleration strength is moderate. In such models, the outflow Q_{out} from traffic jams is a self-organized constant of traffic flow (Kerner et al., 1994, 1996). It corresponds approximately to the intersection point of the linear jam line

$$J(\rho) = \frac{1}{T} \left(1 - \frac{\rho}{\rho_{\text{jam}}} \right) \quad (11)$$

with the free branch of the flow–density diagram, where T denotes the time headway in congested traffic and

ρ_{jam} the density inside traffic jams. The jam line corresponds to the flow-density relation for moving traffic patterns with a self-organized, stationary profile (Kerner & Konhäuser, 1994). These propagate with the velocity $C = -1/(T\rho_{\text{jam}}) \approx -15 \text{ km/h}$, which is another traffic constant. (Once a traffic jam is fully developed, it moves upstream with constant velocity, as vehicles leave the downstream jam front at a constant rate, while new ones join it at the upstream front.)

With this knowledge, one can understand the various congested traffic states observed on freeway sections with bottlenecks (Helbing et al., 1998–2002). Let us assume a bottleneck due to ramp flows $v_+ = Q_{\text{rmp}}/(nL)$, where L is the used length of the on-ramp and n the number of freeway lanes. The corresponding bottleneck strength is, then, $\Delta Q = Q_{\text{rmp}}/n$. If Q_{up} denotes the traffic flow upstream of the bottleneck and $Q_{\text{tot}} = (Q_{\text{up}} + \Delta Q)$ is the total capacity required downstream of the ramp, we will eventually find a growing vehicle queue upstream of the bottleneck, if Q_{tot} is greater than the dynamic capacity Q_{out} . The traffic flow Q_{cong} resulting in the congested area plus the inflow or bottleneck; strength ΔQ are

normally given by the outflow Q_{out} ; that is,

$$Q_{\text{cong}} = Q_{\text{out}} - \Delta Q \tag{12}$$

(if vehicles cannot enter the freeway downstream of the congestion front). One can distinguish the following cases: If the density ρ_{cong} associated with the congested flow

$$Q_{\text{cong}} = Q_*(\rho_{\text{cong}}) \tag{13}$$

lies in the stable range, we find homogeneous congested traffic (HCT) such as typical traffic jams during holiday seasons or after serious accidents. For a smaller on-ramp flow or bottleneck strength ΔQ , the congested flow Q_{cong} is linearly unstable, and we either find oscillating congested traffic (OCT) or triggered stop-and-go traffic (TSG). In contrast to OCT, stop-and-go traffic is characterized by a sequence of moving jams, between which traffic flows freely. This state can either emerge from a spatial sequence of homogeneous and oscillating congested traffic (Koshi et al., 1983; called “pinch effect” by Kerner, 1998), or it can be caused by the inhomogeneity at the ramp. In the latter case, each traffic jam triggers another one by inducing a small

Figure 1. Numerically determined phase diagram of traffic states in the presence of one bottleneck as a function of the upstream flow Q_{up} and the bottleneck strength ΔQ (center right), and empirical representatives for the related kinds of congested traffic (by Martin Schönhof and D. Helbing. Note that the outflow Q_{out} in the applied simulation model depends on the bottleneck strength ΔQ .

perturbation in the inhomogeneous freeway section (see Figure 1), which propagates downstream as long as it is small, but turns back when it has grown large enough (boomerang effect). This, however, requires the downstream traffic flow to be linearly unstable. If it is (meta-)stable instead (when the traffic volume Q_{tot} is further reduced), a traffic jam will usually not trigger a growing perturbation. In that case, one finds either a single moving localized cluster (MLC) or a pinned localized cluster (PLC) at the location of the ramp. The latter requires the traffic flow in the upstream section to be stable, so that no traffic jam can survive there. Finally, for sufficiently small traffic volumes Q_{tot} , we find free traffic (FT), as expected. For freeways with a single bottleneck and a large perturbation of traffic flow, these facts can be summarized by the phase diagram in Figure 1, which is universal for all microscopic and macroscopic, stochastic and deterministic traffic models with the same instability diagram (stable, metastable, and unstable density ranges). Results for more complex freeway geometries, other initial or boundary conditions, and other instability diagrams are available as well.

Current research focuses on the following open questions: Are fluctuations and psychological concepts necessary to understand the empirical observations in traffic flows? Can the large individual variation of time headways fully account for the large scattering of flow-density data in synchronized flow? (In congested traffic flow, the velocities in neighboring lanes are usually synchronized, as different speeds are balanced by lane changes.) What are the site- and country-dependent differences in traffic dynamics, and can they be adequately reflected by different model parameters for the driver-vehicle units? How can the insights regarding the laws of traffic dynamics be used for traffic optimization by variable speed limits, intelligent on-ramp controls, dynamic re-routing, and driver assistance systems? How can they be transferred to the explanation of breakdown and obstruction phenomena in socioeconomic systems?

TURBULENCE

Turbulence is a state of a nonlinear physical system that has energy distribution over many degrees of freedom strongly deviated from equilibrium. Turbulence is irregular both in time and in space. Turbulence can be maintained by some external influence or it can decay on the way to relaxation to equilibrium. The term first appeared in fluid mechanics and was later generalized to include far-from-equilibrium states in solids and plasmas.

If an obstacle of size L is placed in a fluid of viscosity ν that is moving with velocity V , a turbulent wake emerges for sufficiently large values of the Reynolds number

$$\text{Re} \equiv VL/\nu.$$

At large Re , flow perturbations produced at scale L experience a viscous dissipation that is small compared with nonlinear effects. Nonlinearity then induces motions at smaller and smaller scales until viscous dissipation terminates the process at a scale much smaller than L , leading to a wide (so-called inertial) interval of scales where viscosity is negligible and nonlinearity plays a dominant role.

Examples of this phenomenon include waves excited on a fluid surface by wind or moving bodies and waves in plasmas and solids that are excited by external electromagnetic fields. The state of such a system is called turbulent when the wavelength of the waves excited greatly differs from the wavelength of the waves that dissipate. Nonlinear interactions excite waves in the interval of wavelengths (called the transparency window or inertial interval as in fluid turbulence) between the injection and dissipation scales.

The ensuing complicated and irregular dynamics require a statistical description based on averaging over regions of space or intervals of time. Because

nonlinearity dominates in the inertial interval, it is natural to ask to what extent the statistics are universal, in the sense of being independent of the details of excitation and dissipation. The answer to this question is far from evident for nonequilibrium systems. A fundamental physical problem is to establish which statistical properties are universal in the inertial interval of scales and which are features of different turbulent systems.

Constraints on dynamics are imposed by conservation laws, and therefore, conserved quantities must play an essential role in turbulence. Although the conservation laws are broken by pumping and dissipation, these factors do not act in the inertial interval. Under incompressible turbulence, for example, the kinetic energy is pumped by external forcing and is dissipated by viscosity. As suggested by Lewis Fry Richardson in 1921, kinetic energy flows throughout the inertial interval of scales in a cascade-like process. The cascade idea explains the basic macroscopic manifestation of turbulence: the rate of dissipation of the dynamical integral of motion has a finite limit when the dissipation coefficient tends to zero. In other words, the mean rate of the viscous energy dissipation does not depend on viscosity at large Reynolds numbers. That means that symmetry of the inviscid equation (here, time-reversal invariance) is broken by the presence of the viscous term, even though the latter might have been expected to become negligible in the limit $\text{Re} \rightarrow \infty$.

The cascade idea fixes only the mean flux of the respective integral of motion, requiring it to be constant across the inertial interval of scales. To describe an entire turbulence statistics, one has to solve problems on a case-by-case basis with most cases still unsolved.

Weak Wave Turbulence

From a theoretical point of view, the simplest case is the turbulence of weakly interacting waves. Examples include waves on the water surface, waves in plasma with and without a magnetic field, and spin waves in magnetics. We assume spatial homogeneity and denote by a_k the amplitude of the wave with the wave vector $\mathbf{k}$. When the amplitude is small, it satisfies the linear equation

$$\frac{\partial a_k}{\partial t} = -i\omega_k a_k + f_k(t) - \gamma_k a_k. \quad (1)$$

Here, the dispersion law ω_k describes wave propagation, γ_k is the decrement of linear damping, and f_k describes pumping. For the linear system, a_k is different from zero only in the regions of $\mathbf{k}$ -space where f_k is nonzero. To describe wave turbulence that involves wave numbers outside the pumping region, one must account for the interactions among different waves. Considering the wave system to be closed (no external pumping or dissipation), one can describe it as a

Hamiltonian system using wave amplitudes as normal canonical variables (Zakharov et al., 1992). At small amplitudes, the Hamiltonian can be written as an expansion over a_k , where the second-order term describes noninteracting waves and high-order terms determine the interaction

$$H = \int \omega_k |a_k|^2 d\mathbf{k} + \int \left(V_{123} a_1 a_2^* a_3^* + \text{c.c.} \right) \delta(\mathbf{k}_1 - \mathbf{k}_2 - \mathbf{k}_3) d\mathbf{k}_1 d\mathbf{k}_2 d\mathbf{k}_3 + O(a^4). \quad (2)$$

Here, $V_{123} = V(\mathbf{k}_1, \mathbf{k}_2, \mathbf{k}_3)$ is the interaction vertex, and c.c. denotes complex conjugate. In this expansion, we presume every subsequent term smaller than the previous one, in particular, $\xi_k = |V_{kkk} a_k| k^d / \omega_k \ll 1$. Wave turbulence that satisfies that condition is called weak turbulence. Also, space dimensionality d can be 1, 2, or 3.

A dynamic equation that accounts for pumping, damping, wave propagation, and interaction thus has the following form:

$$\frac{\partial a_k}{\partial t} = -i \frac{\delta H}{\delta a_k^*} + f_k(t) - \gamma_k a_k. \quad (3)$$

It is likely that the statistics of the weak turbulence at $k \gg k_f$ is close to Gaussian for wide classes of pumping statistics (this has not been shown rigorously). It is definitely the case for a random force with the statistics close to Gaussian. We consider here and below a pumping by a Gaussian random force statistically isotropic and homogeneous in space and white in time. Thus,

$$\langle f_k(t) f_{k'}^*(t') \rangle = F(k) \delta(\mathbf{k} + \mathbf{k}') \delta(t - t'), \quad (4)$$

where angular brackets imply spatial averages, and $F(k)$ is assumed nonzero only around some k_f . For waves to be well defined, we assume $\gamma_k \ll \omega_k$.

Because the dynamic equation (3) contains a quadratic nonlinearity, the statistical description in terms of moments encounters the closure problem: the time derivative of the second moment is expressed via the third one, the time derivative of the third moment is expressed via the fourth one, and so on. Fortunately, weak turbulence in the inertial interval is expected to have the statistics close to Gaussian, so one can express the fourth moment as the product of two second ones. As a result, one gets a closed kinetic equation for the single-time pair correlation function $\langle a_k a_{k'} \rangle = n_k \delta(\mathbf{k} + \mathbf{k}')$ (Zakharov et al., 1992):

$$\begin{aligned} \frac{\partial n_k}{\partial t} &= F_k - \gamma_k n_k + I_k^{(3)}, \\ I_k^{(3)} &= \int (U_{k12} - U_{1k2} - U_{2k1}) d\mathbf{k}_1 d\mathbf{k}_2, \\ U_{123} &= \pi [n_2 n_3 - n_1 (n_2 + n_3)] |V_{123}|^2 \\ &\quad \times \delta(\mathbf{k}_1 - \mathbf{k}_2 - \mathbf{k}_3) \delta(\omega_1 - \omega_2 - \omega_3). \end{aligned} \quad (5)$$

This is called the kinetic equation for waves. The collision integral $I_k^{(3)}$ describes three-wave interactions: the first term in the integral corresponds to a decay of a given wave while the second and third terms correspond to a confluence with other waves.

One can estimate from (5) the inverse time of nonlinear interaction at a given k as $|V(k, k, k)|^2 n(k) k^d / \omega(k)$. We define k_d as the wave number where this inverse time is comparable with $\gamma(k)$ and assume nonlinearity to dominate over dissipation at $k \ll k_d$. As has been noted, wave turbulence appears when there is a wide (inertial) interval of scales where both pumping and damping are negligible, which requires $k_d \gg k_f$, the condition analogous to $\text{Re} \gg 1$.

The presence of the frequency delta-function in $I_k^{(3)}$ means that wave interaction conserves the quadratic part of the energy $E = \int \omega_k n_k d\mathbf{k} = \int E_k d\mathbf{k}$. For the cascade picture to be valid, the collision integral has to converge in the inertial interval which means that energy exchange is small between motions of vastly different scales, a property called interaction locality in k -space. Consider now a statistical steady state established under the action of pumping and dissipation. Let us multiply (5) by ω_k and integrate it over either interior or exterior of the ball with radius k . Taking $k_f \ll k \ll k_d$, one sees that the energy flux through any spherical surface (Ω is a solid angle),

$$P_k = \int_0^k k^{d-1} dk \int d\Omega \omega_k I_k^{(3)},$$

is constant in the inertial interval and is equal to the energy production/dissipation rate:

$$P_k = \varepsilon = \int \omega_k F_k d\mathbf{k} = \int \gamma_k E_k d\mathbf{k}. \quad (6)$$

Let us assume now that the medium (characterized by ω_k and V_{123}) can be considered isotropic at the scales in the inertial interval. In addition, for scales much larger or much smaller than a typical scale in the medium (like the Debye radius in plasma or the depth of the water), the Hamiltonian coefficients are usually scale invariant: $\omega(k) = ck^\alpha$ and $|V(\mathbf{k}, \mathbf{k}_1, \mathbf{k}_2)|^2 = V_0^2 k^{2m} \chi(k_1/k, k_2/k)$ with $\chi \simeq 1$. Remember that we presumed statistically isotropic force. In this case, the pair correlation function that describes a steady cascade is also isotropic and scale invariant:

$$n_k \simeq \varepsilon^{1/2} V_0^{-1} k^{-m-d}. \quad (7)$$

One can show that (7) reduces $I_k^{(3)}$ to zero (see Zakharov et al., 1992).

If the dispersion relation $\omega(k)$ does not allow for the resonance condition $\omega(k_1) + \omega(k_2) = \omega(|\mathbf{k}_1 + \mathbf{k}_2|)$, then the three-wave collision integral is zero and one has to account for four-wave scattering which is always resonant; that is, whatever $\omega(k)$ one can

always find four wave vectors that satisfy $\omega(k_1) + \omega(k_2) = \omega(k_3) + \omega(k_4)$ and $\mathbf{k}_1 + \mathbf{k}_2 = \mathbf{k}_3 + \mathbf{k}_4$. The collision integral that describes scattering,

$$I_k^{(4)} = \frac{\pi}{2} \int |T_{k123}|^2 [n_2 n_3 (n_1 + n_k) - n_1 n_k (n_2 + n_3)] \delta(\mathbf{k} + \mathbf{k}_1 - \mathbf{k}_2 - \mathbf{k}_3) \times \delta(\omega_k + \omega_1 - \omega_2 - \omega_2) d\mathbf{k}_1 d\mathbf{k}_2 d\mathbf{k}_3, \quad (8)$$

conserves the energy and also the wave action $N = \int n_k d\mathbf{k}$ (which can also be called the number of waves). Pumping generally provides for an input of both E and N . If there are two inertial intervals (at $k \gg k_f$ and $k \ll k_f$), then there should be two cascades. Indeed, if $\omega(k)$ grows with k , then absorbing finite amount of E at $k_d \rightarrow \infty$ corresponds to an absorption of an infinitely small N . It is thus clear that the flux of N has to go in the opposite direction, that is, to small wave numbers. A so-called inverse cascade with a constant flux of N can thus be realized at $k \ll k_f$. A sink at small k can be provided by wall friction in the container or by long waves leaving the turbulent region in open spaces (as in sea storms).

The collision integral $I_k^{(3)}$ involves products of two n_k , so that flux constancy requires $E_k \propto \varepsilon^{1/2}$ while for the four-wave case, one has $E_k \propto \varepsilon^{1/3}$. In many cases (when there is complete self-similarity), that knowledge is sufficient to obtain the scaling of E_k from a dimensional reasoning without actually calculating V and T . For example, short waves in deep water are characterized by the surface tension σ and density ρ , so the dispersion relation must be $\omega_k \sim \sqrt{\sigma k^3 / \rho}$, which allows for the three-wave resonance and thus $E_k \sim \varepsilon^{1/2} (\rho \sigma)^{1/4} k^{-7/4}$. For long waves in deep water, the surface-restoring force is dominated by gravity, so that the gravitational acceleration g replaces σ as a defining parameter and $\omega_k \sim \sqrt{gk}$. Such a dispersion law does not allow for three-wave resonance, so that the dominant interaction is four-wave scattering which permits two cascades. The direct energy cascade corresponds to $E_k \sim \varepsilon^{1/3} \rho^{2/3} g^{1/2} k^{-5/2}$. The inverse cascade carries the flux of N which we denote Q ; it has the dimensionality $[Q] = [\varepsilon]/[\omega_k]$ and corresponds to $E_k \sim Q^{1/3} \rho^{2/3} g^{2/3} k^{-7/3}$.

Because the statistics of weak turbulence is near Gaussian, it is completely determined by the pair correlation function, which is in turn determined by the respective flux. We thus conclude that weak turbulence is universal in the inertial interval.

Strong Wave Turbulence

One cannot treat wave turbulence as a set of weakly interacting waves when the wave amplitudes are large ($\xi_k \geq 1$) and also in the particular case of linear

(acoustic) dispersion where $\omega(k) = ck$ for arbitrarily small amplitudes. Indeed, there is no dispersion of wave velocity for acoustic waves, so waves moving in the same direction interact strongly and produce shock waves when viscosity is small. Formally, there is a singularity due to the coinciding arguments of delta-functions in (5) (and in the higher terms of perturbation expansion for $\partial n_k / \partial t$), which is thus invalid at however small amplitudes. Still, some features of the statistics of acoustic turbulence can be understood even without a closed description.

Consider a one-dimensional case which pertains, for instance, to sound propagating in long pipes. Because weak shocks are stable with respect to transverse perturbations (Landau & Lifshitz, 1987), quasi-one-dimensional perturbations may propagate in two and three dimensions as well. In a reference frame that moves with the sound velocity, weakly compressible 1-d flows ($u \ll c$) are described by the Burgers equation (Landau & Lifshitz, 1987)

$$u_t + uu_x - \nu u_{xx} = 0. \quad (9)$$

The Burgers equation has a propagating shock-wave solution $u = 2\nu \{1 + \exp[\nu(x - vt)/\nu]\}^{-1}$ with the energy dissipation rate $\nu \int u_x^2 dx$ independent of ν . The shock width ν/ν is a dissipative scale, and we consider acoustic turbulence produced by a pumping correlated on much larger scales (i.e., pumping a pipe from one end by frequencies much less than cv/ν). After some time, the system will develop shocks at random positions. Here we consider the single-time statistics of the Galilean invariant velocity difference $\delta u(x, t) = u(x, t) - u(0, t)$. The moments of δu are called structure functions $S_n(x, t) = \langle [u(x, t) - u(0, t)]^n \rangle$. Quadratic nonlinearity allows the time derivative of the second moment to be expressed via the third one:

$$\frac{\partial S_2}{\partial t} = -\frac{\partial S_3}{\partial x} - 4\varepsilon + \nu \frac{\partial^2 S_2}{\partial x^2}. \quad (10)$$

Here $\varepsilon = \nu \langle u_x^2 \rangle$ is the mean energy dissipation rate. Equation (10) describes both a free decay (when ε depends on t) and the case of a permanently acting pumping which generates turbulence statistically steady at scales less than the pumping length.

In the first case, $\partial S_2 / \partial t \approx S_2 u / L \ll \varepsilon \approx u^3 / L$ (where L is a typical distance between shocks); while in the second case, $\partial S_2 / \partial t = 0$ so that $S_3 = 12\varepsilon x + \nu \partial S_2 / \partial x$. Consider now the limit $\nu \rightarrow 0$ at fixed x (and t for decaying turbulence). Shock dissipation provides for a finite limit of ε at $\nu \rightarrow 0$, then

$$S_3 = -12\varepsilon x. \quad (11)$$

This formula is a direct analog of (6). Indeed, the Fourier transform of (10) describes the energy density

$E_k = \langle |u_k|^2 \rangle / 2$: $(\partial_t - \nu k^2)E_k = -\partial P_k / \partial k$ where the k -space flux

$$P_k = \int_0^k dk' \int_{-\infty}^{\infty} dx S_3(x) k' \sin(k'x) / 24.$$

It is thus the flux constancy that fixes $S_3(x)$ which is universal (determined solely by ε) and depends neither on the initial statistics for decay nor on the pumping for steady turbulence. On the contrary, other structure functions $S_n(x)$ are not given by $(\varepsilon x)^{n/3}$. Indeed, the scaling of the structure functions can be readily understood for any dilute set of shocks (that is, when shocks do not cluster in space) which seems to be the case for both smooth initial conditions and large-scale pumping in Burgers turbulence. In this case, $S_n(x) \sim C_n |x|^n + C'_n |x|$, where the first term comes from the regular (smooth) parts of the velocity while the second comes from $O(x)$ probability to have a shock in the interval x . The scaling exponents, $\xi_n = d \ln S_n / d \ln x$, thus behave as follows: $\xi_n = n$ for $n \leq 1$ and $\xi_n = 1$ for $n > 1$. That means that the probability density function (PDF) of the velocity difference in the inertial interval $P(\delta u, x)$ is not scale-invariant; that is, the function of the rescaled velocity difference $\delta u/x^a$ cannot be made scale-independent for any a . As one goes to smaller scales, the lower-order moments decrease faster than the higher-order ones, that means that the smaller the scale the more probable are large fluctuations. In other words, the level of fluctuations increases with the resolution. When the scaling exponents ξ_n do not lie on a straight line, this is called an anomalous scaling since it is related again to the symmetry (scale invariance) of the PDF broken by pumping and not restored even when $x/L \rightarrow 0$. As an alternative to the description in terms of structures (shocks), one can relate the anomalous scaling in Burgers turbulence to the additional integrals of motion. Indeed, the integrals $E_n = \int u^{2n} dx / 2$ are all conserved by the inviscid Burgers equation. Any shock dissipates the finite amount of E_n at the limit $\nu \rightarrow 0$, so that similar to (11), one denotes $\langle \dot{E}_n \rangle = \varepsilon_n$ and obtains $S_{2n+1} = -4(2n+1)\varepsilon_n x / (2n-1)$ for integer n .

Note that $S_2(x) \propto |x|$ corresponds to $E(k) \propto k^{-2}$, which is natural since every shock gives $u_k \propto 1/k$ at $k \ll \nu/\nu$; that is, the energy spectrum is determined by the type of structures (shocks) rather than by energy flux constancy. Similar ideas were suggested for other types of strong wave turbulence assuming them to be dominated by different structures. Weak wave turbulence, being a set of weakly interacting plane waves, can be studied uniformly for different systems (Zakharov et al., 1992). On the contrary, when nonlinearity is comparable with or exceeds dispersion, different structures appear in different systems. Identifying structures and the role they play in determining different statistical characteristics of strong wave turbulence remains to be investigated for most cases. Broadly, one distinguishes conservative

structures (like solitons and vortices) from dissipative structures which usually appear as a result of finite-time singularity of the nondissipative equations (like shocks, light self-focusing, or wave collapse). For example, nonlinear wave packets are described by the nonlinear Schrödinger equation,

$$i\psi_t + \Delta\psi + T|\psi|^2\psi = 0. \quad (12)$$

Weak wave turbulence is determined by $|T|^2$ and is the same for both $T < 0$ (wave repulsion) and $T > 0$ (wave attraction). At high levels of nonlinearity, different signs of T correspond to dramatically different physics: At $T < 0$, one has a stable condensate, solitons, and vortices, while at $T > 0$, instabilities dominate and wave collapse is possible at $d = 2, 3$. No analytic theory is yet available for strong turbulence described by (12).

Because the parameter of nonlinearity $\xi(k)$ generally depends on k , then there may exist a weakly turbulent cascade until some k_* where $\xi(k_*) \sim 1$, and strong turbulence beyond this, wave number; thus weak and strong turbulence can coexist in the same system. Presuming that some mechanism (for instance, wave breaking) prevents the appearance of wave amplitudes that correspond to $\xi_k \gg 1$, one may hypothesize that some cases of strong turbulence correspond to the balance between dispersion and nonlinearity local in k -space so that $\xi(k)$ is constant throughout its domain in k -space. That would correspond to the spectrum $E_k \sim \omega_k^2 k^{-d} / |V_{kkk}|^2$ which is ultimately universal, that is, independent even of the flux (only the boundary k_* depends on the flux). For gravity waves, this gives $E_k = \rho g k^{-3}$, the same spectrum one obtains presuming the wave profile to have cusps (another type of dissipative structure leading to whitecaps in stormy seas—see Phillips, 1977). It is unclear if such flux-independent spectra are realized.

Incompressible Turbulence

Incompressible fluid flow is described by the Navier–Stokes equation

$$\partial_t \mathbf{v}(\mathbf{r}, t) + \mathbf{v}(\mathbf{r}, t) \cdot \nabla \mathbf{v}(\mathbf{r}, t) - \nu \nabla^2 \mathbf{v}(\mathbf{r}, t) = -\nabla p(\mathbf{r}, t), \quad \text{div } \mathbf{v} = 0.$$

We are again interested in the structure functions $S_n(\mathbf{r}, t) = \langle [(\mathbf{v}(\mathbf{r}, t) - \mathbf{v}(0, t)) \cdot \mathbf{r}/r]^n \rangle$ and treat first the three-dimensional case. Similar to (10), one considers distance r smaller than the force correlation scale for a steady case and smaller than the size of the turbulent region for a decay case. For such r , one can derive the Karman–Howarth relation between S_2 and S_3 (see Landau & Lifshitz, 1987):

$$\frac{\partial S_2}{\partial t} = -\frac{1}{3r^4} \frac{\partial}{\partial r} (r^4 S_3) + \frac{4\varepsilon}{3} + \frac{2\nu}{r^4} \frac{\partial}{\partial r} \left(r^4 \frac{\partial S_2}{\partial r} \right). \quad (13)$$

Here $\varepsilon = \nu \langle (\nabla \mathbf{v})^2 \rangle$ is the mean energy dissipation rate. Neglecting the time derivative (which is zero in a steady state and small compared with ε for decaying turbulence), one can multiply (13) by r^4 and integrate $S_3(r) = -4\varepsilon r/5 + 6\nu dS_2(r)/dr$. Andrei Kolmogorov in 1941 considered the limit $\nu \rightarrow 0$ for fixed r and assumed nonzero limit for ε , which gives the so-called $\frac{4}{5}$ law (see Landau & Lifshitz, 1987; Frisch, 1995):

$$S_3 = -\frac{4}{5} \varepsilon r. \quad (14)$$

This relation is a direct analog of (6) and (11). It also means that the kinetic energy has a constant flux in the inertial interval of scales (the viscous scale η is defined by $\nu S_2(\eta) \simeq \varepsilon \eta^2$). Law (14) implies that the third-order moment is universal; that is, it does not depend on the details of the turbulence production but is determined solely by the mean energy dissipation rate. The rest of the structure functions have not yet been derived. Kolmogorov (and also Werner Heisenberg, Karl von Weizsacker, and Lars Onsager) presumed the pair correlation function to be determined only by ε and r which would give $S_2(r) \sim (\varepsilon r)^{2/3}$ and the energy spectrum $E_k \sim \varepsilon^{2/3} k^{-5/3}$. Experiments suggest that $\zeta_n = d \ln S_n / d \ln r$ lie on a smooth concave curve sketched in Figure 1. While ζ_2 is close to $2/3$, it has to be a bit larger because experiments show that the slope at zero $d\zeta_n/dn$ is larger than $\frac{1}{3}$ while $\zeta(3) = 1$ in agreement with (14). As in Burgers turbulence, the PDF of velocity differences in the inertial interval is not scale-invariant in 3-d incompressible turbulence. No one has yet found an explicit relation between the anomalous scaling for 3-d Navier–Stokes turbulence and either structures or additional integrals of motion.

While not exact, the Kolmogorov approximation $S_2(\eta) \simeq (\varepsilon \eta)^{2/3}$ can be used to estimate the viscous scale: $\eta \simeq L \text{Re}^{-3/4}$. The number of degrees of freedom involved in 3-d incompressible turbulence can thus be roughly estimated as $N \sim (L/\eta)^3 \sim \text{Re}^{9/4}$. That means, in particular, that detailed computer simulation of water or oil pipe flows ($\text{Re} \sim 10^4 - 10^7$) or turbulent clouds ($\text{Re} \sim 10^6 - 10^9$) is out of question for the foreseeable future. To calculate correctly at least the large-scale part of the flow, it is desirable to have some theoretical model to parametrize the small-scale motions, the main obstacle being our lack of qualitative understanding and quantitative description of how turbulence statistics changes as one goes downscale.

Large-scale motions in a shallow fluid can be approximately considered two dimensional. When the velocities of such motions are much smaller than the velocities of the surface waves and the velocity of sound, such flows can be considered incompressible. Their description is important for understanding atmospheric and oceanic turbulence at the scales larger than atmosphere height and ocean depth.

Figure 1. The scaling, exponents of the structure functions ξ_n for Burgers, ζ_n for Navier–Stokes, and σ_n for the passive scalar. The dotted straight line is the Kolmogorov hypothesis $n/3$.

Vorticity $\omega = \text{curl } \mathbf{v}$ is a scalar in a two-dimensional flow. It is advected by the velocity field and dissipated by viscosity. Taking the curl of the Navier–Stokes equation, one gets

$$\partial_t \omega + (\mathbf{v} \cdot \nabla) \omega = \nu \nabla^2 \omega. \tag{15}$$

Two-dimensional incompressible inviscid flow just transports vorticity from place to place and thus conserves spatial averages of any function of vorticity. In particular, we now have the second quadratic inviscid invariant (in addition to energy) which is called enstrophy: $\int \omega^2 d\mathbf{r}$. Since the spectral density of the energy is $|v_k|^2/2$ while that of the enstrophy is $|k \times v_k|^2$, Robert Kraichnan suggested in 1967 that the direct cascade (towards large k) is that of enstrophy while the inverse cascade is that of energy. Again, for the inverse energy cascade, there is no consistent theory except for the flux relation that can be derived similar to (14):

$$S_3(r) = 4\epsilon r/3. \tag{16}$$

The inverse cascade is observed in the atmosphere (at scales of 30–500 km) and in laboratory experiments. Experimental data suggest that there is no anomalous scaling; thus, $S_n \propto r^{n/3}$. In particular, $S_2 \propto r^{2/3}$ which corresponds to $E_k \propto k^{-5/3}$. It is ironic that probably the most widely known statement on turbulence, the $\frac{5}{3}$ spectrum suggested by Kolmogorov for the 3-d case, is not correct in this case (even though the true scaling is close), while it is probably exact in Kraichnan’s inverse 2-d cascade. Qualitatively, it is likely that the absence of anomalous scaling in the inverse cascade is associated with the growth of the typical turnover time (estimated, say, as $r/\sqrt{S_2}$) with the scale. As the inverse cascade proceeds, the fluctuations have enough time to get smoothed out as opposed to the direct cascade in three dimensions, where the turnover time decreases in the direction of the cascade.

Before discussing the direct (enstrophy) cascade, we describe a similar yet somewhat simpler problem of passive scalar turbulence, which allows one to introduce the necessary notions of Lagrangian description of the fluid flow. Consider a scalar quantity $\theta(\mathbf{r}, t)$ that is subject to molecular diffusion and advection by the fluid flow but has no back influence on the velocity (i.e., is passive):

$$\partial_t \theta + (\mathbf{v} \cdot \nabla) \theta = \kappa \nabla^2 \theta + \varphi. \tag{17}$$

Here κ is molecular diffusivity. In the same 2-d flow, ω and θ behave in the same way, but vorticity is related to velocity while the passive scalar is not. Examples of passive scalar are smoke in air, salinity in water, and temperature when one neglects thermal convection. If the source φ produces fluctuations of θ on some scale L , then the inhomogeneous velocity field stretches, contracts, and folds the field θ producing progressively smaller and smaller scales. If the rms velocity gradient is Λ , then molecular diffusion is substantial at scales less than the diffusion scale $r_d = \sqrt{\kappa/\Lambda}$. The ratio

$$\text{Pe} = L/r_d$$

is called the Péclet number. It is an analog of the Reynolds number for passive scalar turbulence. When $\text{Pe} \gg 1$, there is a long inertial interval where the flux constancy relation derived by A.M. Yaglom in 1949 holds,

$$\langle (\mathbf{v}_1 \cdot \nabla_1 + \mathbf{v}_2 \cdot \nabla_2) \theta_1 \theta_2 \rangle = 2P, \tag{18}$$

where $P = \kappa \langle (\nabla \theta)^2 \rangle$ and subscripts denote the spatial points. In considering the passive scalar problem, the velocity statistics is presumed to be given. Still, the correlation function (18) mixes $\mathbf{v}$ and θ and does not generally allow one to make a statement on any correlation function of θ . The proper way to describe the correlation functions of the scalar at scales much larger

than the diffusion scale is to employ the Lagrangian description, that is, to follow fluid trajectories. Indeed, if we neglect diffusion, then Equation (17) can be solved along the characteristics $\mathbf{R}(t)$ which are called Lagrangian trajectories and satisfy $d\mathbf{R}/dt = \mathbf{v}(\mathbf{R}, t)$. Presuming zero initial conditions at $t \rightarrow -\infty$, we write

$$\theta(\mathbf{R}(t), t) = \int_{-\infty}^t \varphi(\mathbf{R}(t'), t') dt'. \quad (19)$$

In that way, the correlation functions of the scalar $F_n = \langle \theta(\mathbf{r}_1, t) \dots \theta(\mathbf{r}_n, t) \rangle$ can be obtained by integrating the correlation functions of the pumping along the trajectories that satisfy the final conditions $\mathbf{R}_i(t) = \mathbf{r}_i$.

Consider first, the case of pumping which is Gaussian, statistically homogeneous, and isotropic in space and white in time: $\langle \varphi(\mathbf{r}_1, t_1) \varphi(\mathbf{r}_2, t_2) \rangle = \Phi(|\mathbf{r}_1 - \mathbf{r}_2|) \delta(t_1 - t_2)$ where the function Φ is constant at $r \ll L$ and goes to zero at $r \gg L$. The pumping provides for symmetry $\theta \rightarrow -\theta$ which makes only even correlation functions F_{2n} nonzero. The pair correlation function is

$$F_2(r, t) = \int_{-\infty}^t \Phi(R_{12}(t')) dt'. \quad (20)$$

Here $R_{12}(t') = |\mathbf{R}_1(t') - \mathbf{R}_2(t')|$ is the distance between two trajectories and $R_{12}(t) = r$. The function Φ essentially restricts the integration to the time interval when the distance $R_{12}(t') \leq L$. Simply speaking, the stationary pair correlation function of a tracer is $\Phi(0)$ (which is twice the injection rate of θ^2) times the average time $T_2(r, L)$ that two fluid particles spend within the correlation scale of the pumping. The larger r , the less time it takes for the particles to separate from r to L and the smaller is $F_2(r)$. Of course, $T_{12}(r, L)$ depends on the properties of the velocity field. A general theory is available only when the velocity field is spatially smooth at the scale of scalar pumping L . This so-called Batchelor regime happens, in particular, when the scalar cascade occurs at the scales less than the viscous scale of fluid turbulence. This requires the Schmidt number ν/κ (called the Prandtl number when θ is temperature) to be large, which is the case for very viscous liquids. In this case, one can approximate the velocity difference $\mathbf{v}(\mathbf{R}_1, t) - \mathbf{v}(\mathbf{R}_2, t) \approx \hat{\sigma}(t)\mathbf{R}_{12}(t)$ with the Lagrangian strain matrix $\sigma_{ij}(t) = \nabla_j v_i$. In this regime, the distance obeys the linear differential equation

$$\dot{\mathbf{R}}_{12}(t) = \hat{\sigma}(t)\mathbf{R}_{12}(t). \quad (21)$$

The theory of such equations is well developed and related to what is called Lagrangian chaos, as fluid trajectories separate exponentially as is typical for systems with dynamical chaos (see, e.g., Falkovich et al., 2001): At t much larger than the correlation time of the random process $\hat{\sigma}(t)$, all moments of R_{12} grow exponentially with time and $\langle \ln[R_{12}(t)/R_{12}(0)] \rangle = \lambda t$,

where λ is called a senior Lyapunov exponent of the flow (note that for the description of the scalar we need the flow taken backwards in time which is different from that taken forward because turbulence is irreversible). Dimensionally, $\lambda = \Delta f(\text{Re})$ where the limit of the function f at $\text{Re} \rightarrow \infty$ is unknown. We thus obtain

$$F_2(r) = \Phi(0)\lambda^{-1} \ln(L/r) = 2P\lambda^{-1} \ln(L/r). \quad (22)$$

In a similar way, one shows that for $n \ll \ln(L/r)$, all F_n are expressed via F_2 and the structure functions $S_{2n} = \langle [\theta(\mathbf{r}, t) - \theta(0, t)]^{2n} \rangle \propto \ln^n(r/r_d)$ for $n \ll \ln(r/r_d)$. This can be generalized for an arbitrary statistics of pumping as long as it is finite-correlated in time (Falkovich et al., 2001).

One can use the analogy between passive scalar and vorticity in two dimensions as has been shown by Falkovich and Lebedev in 1994 following the line suggested by Kraichnan in 1967. For the enstrophy cascade, one derives the flux relation analogous to (18):

$$\langle (\mathbf{v}_1 \cdot \nabla_1 + \mathbf{v}_2 \cdot \nabla_2) \omega_1 \omega_2 \rangle = 2D, \quad (23)$$

where $D = \langle \nu(\nabla \omega)^2 \rangle$. The flux relation along with $\omega = \text{curl } \mathbf{v}$ suggests the scaling $\delta v(r) \propto r$, that is, velocity being close to spatially smooth (of course, it cannot be perfectly smooth to provide for a nonzero vorticity dissipation in the inviscid limit, but the possible singularities are indeed shown to be no stronger than logarithmic). That makes the vorticity cascade similar to the Batchelor regime of passive scalar cascade with a notable change in that the rate of stretching λ acting on a given scale is not a constant but is logarithmically growing when the scale decreases. Since λ scales as vorticity, the law of renormalization can be established from dimensional reasoning, and one gets $\langle \omega(\mathbf{r}, t) \omega(0, t) \rangle \sim [D \ln(L/r)]^{2/3}$ which corresponds to the energy spectrum $E_k \propto D^{2/3} k^{-3} \ln^{-1/3}(kL)$. Higher-order correlation functions of vorticity are also logarithmic, for instance, $\langle \omega^n(\mathbf{r}, t) \omega^n(0, t) \rangle \sim [D \ln(L/r)]^{2n/3}$. Note that both passive scalar in the Batchelor regime and vorticity cascade in two dimensions are universal, that is, determined by the single flux (P and D , respectively) despite the existence of higher-order conserved quantities. Experimental data and numeric simulations support these conclusions.

Zero Modes and Anomalous Scaling

Let us now return to the Lagrangian description and discuss it when velocity is not spatially smooth, for example, that of the energy cascades in the inertial interval. One can assume that it is Lagrangian statistics that are determined by the energy flux when the distances between fluid trajectories are in the inertial interval. That assumption leads, in particular, to the Richardson law for the asymptotic growth of the

interparticle distance:

$$\langle R_{12}^2(t) \rangle \sim \varepsilon t^3, \quad (24)$$

which was first established from atmospheric observations (in 1926) and later confirmed experimentally for energy cascades both in 3-d and in 2-d. There is no consistent theoretical derivation of (24), and it is unclear whether it is exact (likely to be in 2-d) or just approximate (possible in 3-d). The semi-heuristic argument usually presented in textbooks is based on the mean-field estimate: $\dot{R}_{12} = \delta v(R_{12}, t) \sim (\varepsilon R_{12})^{1/3}$, which upon integration gives $R_{12}^{2/3}(t) - R_{12}^{2/3}(0) \sim \varepsilon^{1/3} t$. For the passive scalar it gives, by virtue of (20), $F_2(r) \sim \Phi(0) \varepsilon^{-1/3} [L^{2/3} - r^{2/3}]$ which was suggested by S. Corrsin and A.M. Oboukhov. The structure function is then $S_2(r) \sim \Phi(0) \varepsilon^{-1/3} r^{2/3}$. Experiments measuring the scaling exponents $\sigma_n = d \ln S_n(r) / d \ln r$ generally give σ_2 close to $2/3$ but higher exponents deviating from the straight line are even stronger than the exponents of the velocity in 3-d. Moreover, the scalar exponents σ_n are anomalous even when advecting velocity has a normal scaling like in the 2-d energy cascade.

To better understand the Lagrangian dynamics (and passive scalar statistics) in a spatially nonsmooth velocity, Kraichnan suggested considering the model of a velocity field as having the simplest statistical and temporal properties, namely Gaussian velocity which is white in time:

$$\begin{aligned} \langle v^i(\mathbf{r}, t) v^j(0, 0) \rangle &= \delta(t) [D_0 \delta_{ij} - d_{ij}(\mathbf{r})], \\ d_{ij} &= D_1 r^{2-\gamma} [(d+1-\gamma) \delta^{ij} + (\gamma-2) r^i r^j r^{-2}]. \end{aligned} \quad (25)$$

Here the exponent $\gamma \in [0, 2]$ is a measure of the velocity nonsmoothness with $\gamma = 0$ corresponding to a smooth velocity and $\gamma = 2$ corresponding to a velocity very rough in space (distributional). Richardson–Kolmogorov scaling of the energy cascade corresponds to $\gamma = 2/3$. Lagrangian flow is a Markov random process for the Kraichnan ensemble (25). Every fluid particle undergoes a Brownian random walk with the so-called eddy diffusivity D_0 . The PDF for two particles to be separated by r after time t satisfies the diffusion equation (see, e.g., Falkovich et al., 2001)

$$\begin{aligned} \partial_t P(r, t) &= L_2 P(r, t), \\ L_2 &= d_{ij}(\mathbf{r}) \nabla^i \nabla^j = D_1 (d-1) r^{1-d} \partial_r r^{d+1-\gamma} \partial_r, \end{aligned} \quad (26)$$

with the scale-dependent diffusivity $D_1 (d-1) r^{2-\gamma}$. The asymptotic solution of (26) is lognormal for the Batchelor case while for $\gamma > 0$

$$P(r, t) = r^{d-1} t^{d/\gamma} \exp(-\text{const } r^\gamma / t). \quad (27)$$

For $\gamma = 2/3$, it reproduces, in particular, the Richardson law. Multiparticle probability distributions also satisfy diffusion equations in the Kraichnan model as well as all the correlation functions of θ . Multiplying equation (17) by $\theta_2 \dots \theta_{2n}$ and averaging over the Gaussian statistics of $\mathbf{v}$ and φ , one derives

$$\begin{aligned} \partial_t F_{2n} &= L_{2n} F_{2n} + \sum_{l,m} F_{2n-2} \Phi(\mathbf{r}_{lm}), \\ L_{2n} &= \sum d_{ij}(\mathbf{r}_{lm}) \nabla_i^l \nabla_m^j. \end{aligned} \quad (28)$$

This equation enables one, in principle, to derive inductively all steady-state F_{2n} starting from F_2 . The equation $\partial_t F_2(r, t) = L_2 F_2(r, t) + \Phi(r)$ has a steady solution $F_2(r) = 2[\Phi(0)/\gamma d(d-1) D_1][d L^\gamma / (d-\gamma) - r^\gamma]$, which has the Corrsin–Oboukhov form for $\gamma = 2/3$. Further, F_4 contains the so-called forced solution having the normal scaling 2γ but also, remarkably, a zero mode Z_4 of the operator L_4 : $L_4 Z_4 = 0$. Such zero modes necessarily appear (to satisfy the boundary conditions at $r \simeq L$) for all $n > 1$, and the scaling exponents of Z_{2n} are generally different from $n\gamma$ that is anomalous. In calculating the scalar structure functions, all terms cancel out except a single zero mode (called irreducible because it involves all distances between $2n$ points). Calculations of Z_n and their scaling exponents σ_n were carried out analytically at $\gamma \ll 1$, $2-\gamma \ll 1$ and $d \gg 1$, and numerically for all γ and $d = 2, 3$ (Falkovich et al., 2001).

That gives σ_n lying on a convex curve (as in Figure 1) which saturates to a constant at large n . Such saturation (confirmed by experiments) is a signature that most singular structures in a scalar field are shocks (as in Burgers turbulence), the value σ_n at $n \rightarrow \infty$ is the fractal codimension of fronts in space. Interestingly, the Kraichnan model enables one to establish the relation between the anomalous scaling and conservation laws of a new type. Thus, the combinations of distances between points that constitute zero modes are the statistical integrals of Lagrangian evolution. To give a simple example, in a Brownian walk, the mean distance between every two particles grows with time, $\langle R_{lm}^2(t) \rangle = R_{lm}^2(0) + \kappa t$, while $\langle R_{lm}^2 - R_{pq}^2 \rangle$ and $\langle 2(d+2) R_{lm}^2 R_{pq}^2 - d(R_{lm}^4 + R_{pq}^4) \rangle$ (and an infinity of similarly built harmonic polynomials) are conserved. Note that the integrals are not dynamical, they are conserved only in average. In a turbulent flow, the form of such conserved quantities is more complicated, but the essence is the same: the increase of averaged distances between fluid particles is compensated by the decrease in shape fluctuations. The existence of statistical conserved quantities breaks the scale invariance of scalar statistics in the inertial interval and explains why scalar turbulence knows more about pumping than just the value of the flux. Note that both symmetries, one broken by pumping (scale invariance) and another by damping (time reversibility) are not restored even when $r/L \rightarrow 0$ and $r_d/r \rightarrow 0$.

For the vector field (like velocity or magnetic field in magnetohydrodynamics), the Lagrangian statistical integrals of motion may involve both the coordinate of the fluid particle and the vector it carries. Such integrals of motion were built explicitly and related to the anomalous scaling for the passively advected magnetic field in the Kraichnan ensemble of velocities (Falkovich et al., 2001). Doing the same for velocity that satisfies the Navier–Stokes equation remains a task for the future.

TURBULENCE, IDEAL

Ideal turbulence (IT) is a mathematical phenomenon that occurs in certain infinite-dimensional deterministic dynamical systems. The attractor of an IT system lies off the phase space, and among the attractor points there are fractal or even random functions. IT is observed in various idealized models of real distributed systems (electrodynamics, acoustics, radiophysics, etc.), and it helps to understand the mathematical scenarios for features of real turbulence. Cascade processes in IT are capable of giving birth to structures of arbitrarily small scale and even causing stochastization of the systems.

A mathematically rigorous definition of ideal turbulence is based on notions of dynamical systems theory and chaos theory. Spatiotemporal chaotization in dynamical systems on spaces of smooth or piecewise smooth functions is perceived as a cascading evolution of such functions with the result that their behavior becomes more and more intricate (see Figure 1), whereupon the limiting states cannot be described with smooth functions. This implies that the attractor of the dynamical system is not contained entirely in the phase space; thus, the dynamical system needs to be extended on a wider functional space so that this new space contains whole “ ω -limit” sets of all or almost all

Figure 1. Start of ideal turbulence: Typical instantaneous distributions of current in a lossless transmission line described by the boundary-value problem $i_x = -Cv_t$, $v_x = -Li_t$, and $v(0, t) = 0$, $i(1, t) = G(v(1, t))$, where i and v are the current and voltage along the line, and G specifies the v - i characteristic of an Esaki (tunnel) diode fixing the boundary condition at $x = 1$.

trajectories. (The ω -limit set of a trajectory is defined as the attractor of the trajectory or, more precisely, as the set of limit points of the trajectory.) The spaces of fractal and random functions are particularly appealing for use as a wider space.

If, with such an extension, the ω -limit set of the trajectory corresponding to some initial state contains a “point” that is a fractal function, then this initial state is said to generate IT. Similarly, if a dynamical system can be extended on a space containing both deterministic and random functions and for some initial state its associated ω -limit set contains a “point” that is a random function, then this initial state is said to generate stochastic ideal turbulence (SIT). If initial states generate IT or SIT, then IT or SIT is said to occur in the dynamical system.

For a space containing fractal functions, one may take the space of multivalued functions with the metric $\rho(\zeta_1, \zeta_2) = \text{dist}_H(\text{gr } \zeta_1, \text{gr } \zeta_2)$, where $\text{dist}_H(\cdot, \cdot)$ is the Hausdorff distance between sets and $\text{gr } \zeta$ denotes the graph of ζ . As any function (deterministic or random) can be interpreted as the collection of all its finite-dimensional distributions, a metric for spaces containing random and deterministic functions is conveniently chosen to compare the distributions of functions (Sharkovsky & Romanenko, 1992).

This classification can be deepened. For instance, an initial state is said to generate weak ideal turbulence (WIT) if it does not generate IT but its associated

ω -limit set contains a function that is multivalued at an infinite number of points.

A simple example of a system with turbulence is the discrete dynamical system acting on the space of smooth functions $\varphi : D \rightarrow E$ according to the rule

$$S : \varphi(x) \mapsto f(\varphi(x)), \quad (1)$$

where $f : E \rightarrow E$ is a smooth function, and D and E are regions of Euclidean spaces. The trajectory through a point φ is the sequence $f^n(\varphi(x))$, $n = 0, 1, 2, \dots$, where the superscript n denotes the n th iteration. Thus, the dynamics of the trajectory can be treated as the dynamics of a continuum of uncoupled oscillators. At every point $x \in D$, there is a "pendulum," oscillating under the law $z_n \mapsto z_{n+1} = f(z_n)$ with $z_0 = \varphi(x)$ and independently of the pendula at other points of D . The independence of the oscillators causes IT in the dynamical systems (1), and moreover, when f has the property of sensitive dependence on initial data on some open set $E' \subset E$, those φ such that $\varphi(D) \supset E'$ often generate SIT. In more general situations that occur in applied problems, the oscillation law depends on initial data φ and/or a point $x \in D$; it can also be time-dependent.

A description of long-term properties for the dynamical systems (1) is most advantageous when f is a one-dimensional map, and D and E are intervals, whereupon one has the following result:

Theorem. *There occur (i) weak ideal turbulence, if f has periodic trajectories of periods 2^i , $0 \leq i \leq l$, with some $l > 1$, and no other periodic trajectories; (ii) ideal turbulence, if f has a periodic trajectory of period $\neq 2^i$, $i = 0, 1, \dots$; and (iii) stochastic turbulence, if f possesses an ergodic smooth invariant measure.*

The map $f : z \mapsto 4z(1-z)$, $z \in [0, 1]$, has an invariant measure with the density $p(z) = 1/\pi\sqrt{z(1-z)}$, and almost each $\varphi : [0, 1] \rightarrow (0, 1)$ generates SIT. Its associated ω -limit set consists of a single point which is the random function with the distribution $F(x, z) = \int_0^z p(z) dz = (2/\pi) \arcsin \sqrt{z}$. Thus the attractor of the dynamical system (1) consists of just this one point. For $f = f_\lambda : z \mapsto \lambda z(1-z)$, $0 < \lambda \leq 4$, there exists a set of positive Lebesgue measure $\Lambda \subset (3, 4]$ such that f_λ with $\lambda \in \Lambda$ has an ergodic smooth invariant measure on $[0, 1]$; hence SIT in the dynamical systems (1) is a non-exclusive phenomenon.

Many evolutionary boundary-value problems (BVPs) for partial differential equations induce dynamical systems of shifts along solutions. It is natural to say that there arises IT or SIT in a BVP if such turbulence occurs in the corresponding dynamical system. The simplest example is the BVP

$$w_t - w_x = 0, \quad 0 \leq x \leq 1, \quad t \geq 0, \quad (2)$$

$$w(1, t) = f(w(0, t)), \quad (3)$$

Figure 2. Towards stochastic turbulence: Typical evolution of flow lines for the vector field (w^1, w^2) given by $w_t^1 = w_x^1 + w^1$, $w_t^2 = -w_x^2 - w^2$, $-\infty < x < +\infty$, $0 \leq y \leq 1$, and $w^1 = w^2|_{y=0}$, $w^1 = f(w^2)|_{y=1}$ with $f(z) = 1 - 2z^2$. The attractor of the BVP consists of one point—the random vector field $(\hat{w}^1, \hat{w}^2)$ whose components have the same (x, y) -independent distribution density $1/2\pi\sqrt{1-z^2}$, $-1 < z < 1$.

where f is a smooth function from some interval E into itself. On the space of smooth functions $\varphi : [0, 1] \rightarrow E$, the BVP induces the dynamical system of shifts $S^t : \varphi(x) \mapsto w_\varphi(x, t)$, $t \geq 0$, where $w_\varphi(x, t)$ is the solution meeting the initial condition $w(x, 0) = \varphi(x)$. For the BVP considered, the shift operator S^t is represented as

$$S^t : \varphi(x) \mapsto f^{(x+t)}(\varphi(\{x+t\})) \quad (4)$$

with $\langle \cdot \rangle$ and $\{ \cdot \}$ being the integer and fractional part of a number, respectively. Thus the dynamical system (4) is a continuous analog of the dynamical system (1), and one can formulate conditions for turbulence in the BVP according to the above theorem.

Replacing (3) with $w_t(1, t) = g(w(0, t))$, $w_t(0, t)$ leads to the dynamical system (4) where f is replaced with $f_{\gamma|\varphi} = f + \gamma|\varphi$, f is an antiderivative of g and $\gamma|\varphi = f(\varphi(0)) - \varphi(1)$. The type of the turbulence arising in a solution $w_\varphi(x, t)$ follows the theorem, as applied to $f_{\gamma|\varphi}$.

BVPs for the wave equation (and related systems) provide examples of ideal turbulence. For the BVP

$$w_{tt} - w_{xx} = 0, \quad 0 \leq x \leq 1, \quad (5)$$

$$w(0, t) = 0, \quad w_t(1, t) = h(w_x(1, t)), \quad (6)$$

its associated shift operator S^t is expressed through a one-dimensional map $f: z_n \mapsto z_{n+1}$, defined implicitly by $z_{n+1} - z_n = h(z_n + z_{n+1})$. This allows one to find conditions for IT or SIT for particular functions h (Sharkovsky, 1994; Sharkovsky et al., 1995). When the conditions of (6) are replaced with $w(0, t) = 0$, $w_x(1, t) = h(w_x(0, t))$, there arises a two-dimensional map defined by $z_{n+1} - z_{n-1} = h(z_n)$.

There are many other one- and many-dimensional BVPs whose dynamics are described in terms of low-dimensional maps, as in the above examples. In these cases, the theory of maps suggests why and how turbulence occurs in the BVP and presents scenarios for self-structuring and self-stochastization. Of importance here are the following properties of maps: the intricate dynamical structure of the basins of attracting cycles, the local self-similarity of the set of points with unstable trajectories, and the occurrence of a smooth invariant measure. Figure 2 is an example of how processes of self-structuring lead to stochastic turbulence.

TURING PATTERNS

As noted by D'Arcy Wentworth Thompson (1917) people in the early 1900s (when the study of symmetry-breaking instabilities was still in its infancy) had already considered the possibility of generating stationary regular concentration patterns through the interplay of diffusion and chemistry. At mid-century, the British mathematician and computing pioneer, Alan Turing, was the first to formulate necessary conditions for the

Figure 1. (a)–(d) Turing structures of different symmetries obtained with the chlorite-iodide-malonic acid reaction. Dark and light regions, respectively, correspond to high and low iodide concentration. The wavelength, a function of kinetic parameters and diffusion coefficients, is of the order of 0.2 mm. All patterns are at the same scale: view size 1.7mm × 1.7mm (Courtesy P. De Kepper, CRPP).

occurrence of space symmetry breaking in the context of biological morphogenesis (Turing, 1952). Following the emergence of the self-oscillating Belousov–Zhabotinsky reaction (Epstein & Pojman, 1998) in the mid-1960s, Ilya Prigogine and coworkers revived Turing's concept, put it on sound thermodynamic and kinetic grounds, and showed that it could only be sustained in continuously fed reactors at a finite distance from equilibrium (Nicolis & Prigogine, 1977).

This work opened up a whole new field of physical chemistry. Many theoretical studies followed, and the diffusive instability that generates such dissipative structures has popped up in other domains of physics and chemistry (Ball, 1999). However, experiments in the chemical realm lagged behind, and it was only in 1989 that the first experimental evidence was obtained by De Kepper and his group (Castets et al., 1990) using the chlorite-iodide-malonic acid reactive system in so-called gel reactors. A recent detailed status of Turing patterns and other symmetry-breaking instabilities in solution chemistry is presented in Borckmans et al. (2002).

The Turing–Prigogine mechanism consists in the spontaneous instability of a homogeneous mixture of chemically reacting species, when some parameter threshold is crossed as one moves away from equilibrium conditions. It leads to stationary, space-periodic patterns for the concentrations of reactants (see Figure 1). In its minimal form, the description of all the systems that exhibit such diffusive instability can formally be cast in the common language of reaction-diffusion systems governed by the set of equations

$$\frac{\partial \mathbf{c}(\mathbf{r}, t)}{\partial t} = \mathbf{f}(\mathbf{c}, b) + \nabla \cdot D \nabla \mathbf{c}(\mathbf{r}, t), \quad (1)$$

where $c(\mathbf{r}, t) \equiv (\dots, c_i, \dots)$ is the local concentration vector, $\mathbf{f}(c, b)$ is a vector function representing the reaction kinetics wherein lies the source of nonlinearity, b stands for a set of control parameters, and D is the matrix of diffusive transport coefficients. Appropriate initial and boundary conditions, in relation with the experimental setup are added to complete the mathematical formulation.

To support such symmetry-breaking instability, the chemical kinetics must involve some type of positive feedback loop controlled at least by an activator species that reinforces its own changes, the latter being counterbalanced by an inhibitory process. Spatial structures can form when the inhibitory effects are transported by diffusion over a larger space range than that of the activating mechanism. An intuitive picture may be obtained when a single activator (A) and inhibitor (H) are present. A autocatalytically promotes its own production and that of H, while the latter opposes the production of A. Consider such system in a nonequilibrium homogeneous steady state (hss) and quench it beyond the instability threshold. The hss then becomes very sensitive. A slight local fluctuation of the concentration of A will increase while it also spreads to the surroundings through diffusion. It will also start producing some H that, however, will diffuse away much faster from the point where the fluctuation occurred as $D_H > D_A$. H thereby hinders the propagation of A. A localized peak of activator surrounded by a barrier of H is thus created. In extended systems, such peaks tend to emerge everywhere, randomly distributed, and their interactions lead to the periodic concentration patterns. The beauty of Turing's idea lies in the counterintuitive organization role of diffusive processes when they compete with the proper autocatalytic chemistry, while diffusion still locally strives to erase any concentration of inhomogeneity.

Theoretical work uses nonlinear kinetic models for $\mathbf{f}(c, b)$ with a limited number of chemical species, typically two or three (Brusselator, Oregonator, CDIMA, etc.). These models stand as a compromise between a minimum of chemical realism and mathematical tractability. For their part, the experimental kinetic schemes usually involve many species, often not fully determined (Epstein & Pojman, 1998).

Analytical work that relies heavily on bifurcation theory (Nicolis & Prigogine, 1977; Manneville, 1990) allows one to determine, through the solution of amplitude equations, which structures of given symmetry are stable for specific conditions (pattern selection). The calculated bifurcation diagrams help to organize the results obtained by straightforward numerical integration of the reaction-diffusion equations. Both types of information may be used to interpret the experimental results. This pattern selection problem was already on Turing's mind when he stated (Turing, 1952): "Most

Figure 2. Schematic representation of a disc-shaped one side fed reactor (OSFR): CSTR (continuous stirred tank reactor), Membrane (mineral disc, pore size 0.02 mm) often placed to protect the gel from mechanical stress produced by the stirrer of the CSTR, Gel, In and Out (input and output ports of chemicals), L (light source), CCD camera.

of an organism, most of the time, is developing from one pattern into another, rather than from homogeneity into a pattern. One would like to be able to follow this more general process mathematically also."

The experimental work takes place in so-called open spatial reactors (Borckmans et al., 2002) which are specifically designed to control the reaction and the structures that eventually develop at a fixed distance from equilibrium and allow probing of the true asymptotic states of the reaction-diffusion systems. Experiments are now usually performed in a one-side fed reactor (OSFR) sketched in Figure 2. The core consists of a piece of soft hydrogel fed by diffusion through one of its faces with chemicals contained in a continuous stirred tank reactor (CSTR), the contents of which are continuously renewed by pumps. The other faces of the gel are pressed against impermeable transparent walls (Plexiglas). Viewing can be practiced both along the feeding axis or orthogonal to it (Ball, 1999; Ouyang & Swinney, 1991). The gel is used to avoid all perturbations induced by the hydrodynamic flows as those associated with the constant supply of fresh reactants, so that only reactive and diffusive processes compete. The necessary diffusion differential between activator and inhibitor species is obtained through the reversible binding of the activator molecules to the large molecular weight color indicator species that is included for visualization purposes. An advantage of such reactors is that they allow for direct correlations to be made between the dynamics of the CSTR, the bifurcation behaviors of which have been extensively studied in the past (Epstein & Pojman, 1998), and that of the gel.

Although scores of papers have been devoted to the application of Turing's idea to biological problems, this speculation remains to be confirmed (Epstein & Pojman, 1998; Borckmans et al., 2002).

TWIST MAP

See Nontwist maps

TWISTOR THEORY

Introduced by Roger Penrose as a geometrical framework for the unification of quantum theory and general relativity (gravity), twistor theory brings out the complex (holomorphic) geometry that underlies real space-time. In general relativity, space-time is a four manifold with metric g . When $g = dt^2 - dx^2 - dy^2 - dz^2$, where (t, x, y, z) are coordinates on $\mathbb{R}^4$, g is said to be flat with signature (1,3) and is called Minkowski space.

The first appearance of a complex structure arises from the fact that at a given event, the celestial sphere of light rays (null directions with respect to g) naturally has the structure of the Riemann sphere, $\mathbb{CP}^1$, in such a way that Lorentz transformations (linear transformations of the tangent space preserving the metric) act on this sphere by Möbius transformations. Twistor space extends this idea to the whole of Minkowski space. Denoted $\mathbb{PT}$, the twistor space for Minkowski space is complex projective three space, $\mathbb{CP}^3$, the space of one-dimensional subspaces of $\mathbb{C}^4$,

it is a three-dimensional complex manifold obtained by adding a “plane at infinity” to $\mathbb{C}^3$. Physically, points of twistor space correspond to spinning massless particles in Minkowski space. Mathematically, the correspondence can be understood as the Klein correspondence.

The Klein Correspondence

The correspondence between $\mathbb{PT}$ and Minkowski space can be extended first to complexified Minkowski space, so that the coordinates are allowed to take on values in $\mathbb{C}$, and then to its conformal compactification by including some points at infinity. It then coincides with the classical complex Klein correspondence. The Klein correspondence is the one-to-one correspondence between lines in $\mathbb{CP}^3$ and points of a four complex-dimensional quadric, $\mathbb{CM}$, in $\mathbb{CP}^5$. The four-quadric $\mathbb{CM}$ can be understood as conformally compactified complexified Minkowski space. Introducing affine coordinates (λ, z_1, z_2) on $\mathbb{PT}$, we find that a line in $\mathbb{PT}$ corresponds to a point (t, x, y, z) by

$$\begin{pmatrix} z_1 \\ z_2 \end{pmatrix} = \begin{pmatrix} t - z & x + iy \\ x - iy & t + z \end{pmatrix} \begin{pmatrix} 1 \\ \lambda \end{pmatrix}.$$

Alternatively, fixing (λ, z_1, z_2) in these equations gives a two-plane in complex Minkowski space corresponding to all the lines in $\mathbb{PT}$ through (λ, z_1, z_2) . Such two-planes are called α -planes. They are totally null (i.e., the tangent vectors not only have zero length but are also mutually orthogonal) and also self-dual (under the differential geometer's notion of Hodge duality).

This complex correspondence can also be restricted to give correspondences for $\mathbb{R}^4$ with metrics of positive definite signature or ultra-hyperbolic (2, 2) signature.

The Penrose Transform

A basic task of twistor theory is to transform solutions to the field equations of mathematical physics into objects on twistor space. This works well for linear massless fields such as the Weyl neutrino equation, Maxwell's equations for electromagnetism, and linearized gravity. In its general form, this transform has become known as the Penrose transform. Such fields correspond to freely prescribable holomorphic functions $f(\lambda, z_1, z_2)$ (or, more precisely, analytic cohomology classes) on regions of twistor space. The field can be obtained from this function by means of a contour integral. The simplest of these integral formulae is

$$\phi(x^a) = \oint f(\lambda, t - z + \lambda(x + iy), x - iy + \lambda(t + z)) d\lambda, \tag{1}$$

and differentiation under the integral sign leads to the fact that ϕ satisfies the wave equation

$$\frac{\partial^2 \phi}{\partial t^2} - \frac{\partial^2 \phi}{\partial x^2} - \frac{\partial^2 \phi}{\partial y^2} - \frac{\partial^2 \phi}{\partial z^2} = 0.$$

Equation (1) was originally discovered by Bateman (1910).

The Penrose transform has found important applications in representation theory and integral geometry. For a review, the reader is referred to Baston and Eastwood (1989), the relevant survey articles in Bailey & Baston (1990) or Chapter 1 of Mason et al. (1990).

Twistor Theory and Nonlinear Equations

The Penrose transform for the Maxwell equations and linearized gravity turns out to be linearizations of correspondences for nonlinear versions of these equations, the Einstein vacuum equations and the Yang–Mills equations, but only in the case that these fields are anti-self-dual. This is the condition that the curvature two-forms satisfy $F^* = -iF$ where $*$ denotes the Hodge dual (which, up to a change of sign, has the effect of interchanging electric and magnetic fields); it is a nonlinear generalization of the right-handed circular polarization condition. In Minkowski signature, the i factor in the anti-self-duality condition implies that real fields cannot be anti-self-dual. Thus, these extensions are not sufficient to fulfill twistor theory's aim of incorporating real basic physics in Minkowski space. However, the factor of i is not present in Euclidean and ultrahyperbolic signature, so the anti-self-duality condition is consistent with real fields in these signatures, and this is where the main applications of these constructions have been.

The Nonlinear Graviton Construction and Its Generalizations

The first nonlinear twistor construction was due to Penrose (1976) and was inspired by Newman's construction of "heavens" from the infinities of asymptotically flat space-times in general relativity (Newman, 1976).

The nonlinear graviton construction proceeds from the definition of twistors in flat space-time as α -planes in complexified Minkowski space. It is natural to ask which complexified metrics admit a full family of α -surfaces, that is, two surfaces that are totally null and self-dual. The answer is that a full family of α -surfaces exists if and only if the conformally invariant part of the curvature tensor, the Weyl tensor, is anti-self-dual. In this case, twistor space can be defined to be the (necessarily three-dimensional) space of such α -surfaces. A remarkable fact is that the twistor space (together with its complex structure) is sufficient to determine the original space-time, and that the

data defining the twistor space is effectively freely prescribable, see Penrose (1976) or Atiyah et al. (1978), for a discussion specialized to Euclidean signature.

There are now large families of extensions, generalizations and reductions of this construction. They are all based on the idea of realizing a space with a given complexified geometric structure as the parameter space of a family of holomorphically embedded submanifolds inside a twistor space. In general, the most useful of these constructions are those in which the "space-time" is obtained as the space of rational curves in a twistor space. This is because the equations that are solved on the corresponding space-time can be thought of as a completely integrable system. See Chapter 13 of Mason & Woodhouse (1996) for a more detailed discussion from this point of view.

The Anti-self-dual Yang–Mills Equations and Its Twistor Correspondence

The anti-self-dual Yang–Mills equations extend Maxwell's equations for electromagnetism in the right circularly polarized case. They are really a family of equations depending on a choice of Lie group G , usually taken to be a group of complex matrices, and Maxwell's equations arise from the case in which $G = U(1)$.

Introduce coordinates x^a , $a = 0, 1, 2, 3$, on $\mathbb{R}^4$ with metric $ds^2 = dx^0 dx^3 + dx^1 dx^2$. The dependent variables are the components A_a of a connection $D_a = \partial_a - A_a$, where $\partial_a = \partial/\partial x^a$ and $A_a = A_a(x^b) \in \text{Lie } G$, the Lie algebra of G . This connection defines a method of differentiating vector valued functions s in some representation of G . The freedom in changing bases for the vector bundle induce the gauge transformations $A_a \rightarrow g^{-1} A_a g - g^{-1} \partial_a g$, $g(x) \in G$ on A_a , and two connections that are related by a gauge transformation are deemed to be the same.

The self-dual Yang–Mills equations are the condition

$$[D_0, D_2] = [D_1, D_3] = [D_0, D_3] + [D_1, D_2] = 0.$$

They are the compatibility conditions $[D_0 + \lambda D_1, D_2 + \lambda D_3] = 0$ for the linear system of equations

$$(D_0 + \lambda D_1)s = (D_2 + \lambda D_3)s = 0, \quad (2)$$

where $\lambda \in \mathbb{C}$ and s is an n -component column vector. These last equations form a Lax pair for the system.

The Ward construction (Ward, 1977) provides a one-to-one correspondence between gauge equivalence classes of solutions of the self-dual Yang–Mills equations and holomorphic vector bundles on regions in twistor space. The key point here is that Equation (2) defines parallel propagation along α -planes. To each point Z in twistor space, we can associate the vector space E_Z of solutions to Equation (2) along

the corresponding α -plane. These vector spaces vary holomorphically with Z , and that is what one means by a vector bundle $E \rightarrow \mathbb{P}^1$. A remarkable fact is that the anti-self-dual Yang–Mills field can be reconstructed up to gauge from E , and E is effectively freely prescribable. See Penrose (1984, 1986); Ward & Wells (1990), or Mason & Woodhouse (1996) for a full discussion, and Atiyah (1979) for a discussion in Euclidean signature.

The Connection with Completely Integrable Systems

In effect, the twistor constructions amount to providing a geometric general local solution to the anti-self-duality equations in the sense that the twistor data is (for a local solution) freely prescribable. Thus, they demonstrate complete integrability of the anti-self-duality equations. The reconstruction of a solution on space-time from twistor data can be hard. In the anti-self-dual Yang–Mills case, it involves the solutions of a Riemann–Hilbert problem, and in the case of the anti-self-dual Einstein equations, the construction of a family of rational curves inside a complex manifold. Nevertheless, such constructions are a familiar part of the apparatus of the theory of integrable systems.

In Ward (1985), this connection with integrable systems was developed further, and the anti-self-dual Yang–Mills equations were shown to yield many important integrable systems under symmetry reduction. Ward's list has been extended and now includes many of the most famous examples of integrable systems such as the Painlevé equations, the Korteweg–de Vries equation, the nonlinear Schrödinger equation, the N -wave equations, among others (see Ablowitz & Clarkson (1992) and Mason & Woodhouse (1996) for a review). There are some notable omissions from the list such as the Kadomtsev–Petviashvili and Davey–Stewartson equations (at least if one restricts oneself to finite-dimensional gauge groups), but the list remains impressive.

One can impose symmetries on the twistor constructions for the anti-self-duality equations to obtain a reduced twistor correspondence for solutions to any of these integrable equations (see Mason & Woodhouse (1996) and Chapter 1 of Mason et al. (1995)), so there are many many twistor correspondences.

Applications

Twistor constructions have the effect of reducing problems in nonlinear differential equations to problems in complex holomorphic geometry, where there are many powerful tools. Twistor theory underlies the many appearances of algebraic geometry, loop groups, and Riemann–Hilbert problems in the theory of integrable systems, even though these structures were, for systems in one and two dimensions, usually discovered

without knowledge of the twistor theory, see Mason & Woodhouse (1996). The most impressive applications of twistor theory have been in three and four dimensions, where it is difficult to imagine making such significant progress without the twistor theory.

The Ward construction was used by Atiyah, Drinfeld, Hitchin, and Manin to construct the Yang–Mills instantons on S^4 ; see Atiyah (1979). Its symmetry reduction was also used by both to obtain monopoles on $\mathbb{R}^3$ and to study the hyperkähler metric on their moduli spaces, see Ward & Wells (1990) and Atiyah and Hitchin (1988) (see Mason & Woodhouse (1996) for further applications).

The nonlinear graviton construction and its generalizations have been used for many constructions of Einstein manifolds and more general anti-self-dual manifolds (see Hitchin (1979) for the construction of asymptotically locally Euclidean hyperkähler spaces in four dimensions). The twistor constructions have also been an important tool in studying general properties, for a twistor construction of an anti-self-dual conformal structure on any manifold that is a connected sum of two other such manifolds (Donaldson & Friedman, 1989). Further applications and developments can be found in Mason et al. (2001).

An application that goes beyond complete integrability is the twistor framework of Merkulov for studying arbitrary geometric structures. This has led to the remarkable classification of all possible irreducible holonomies of torsion-free affine connections (Merkulov & Schwachhöfer, 1999).

It is to be hoped that these many applications will one day feed back into Penrose's original program and provide a unification between quantum theory and gravity.

UNIVERSALITY

The concept of universality serves to emphasize like behavior in seemingly unrelated systems. It became popular in the context of phase transitions when it was noted that after a suitable mapping between the thermodynamic variables, the scaling behavior of spin systems near the critical point depends on the number of spin directions, the dimensionality of the system, and the type and range of interactions only (Griffiths, 1970; Binney et al., 1992). Thus, there is no “universal” universality, but only a restricted one among systems that belong to the same universality class.

A deeper understanding of the empirically established relations emerged within the renormalization group treatment of phase transitions, which allowed identification of the parts of the interactions that are relevant for an assignment to a universality class (Wilson, 1983; Binney et al., 1992).

An elementary example of thermodynamic universality is provided by the law of corresponding states for interacting gases. They can be described over a wide range of temperature T , pressure p , and volume V by the van der Waals equation of state. For one mole of the gas it is

$$(p + a/V^2)(V - b) = RT \quad (1)$$

with R being the gas constant and a and b parameters characteristic of the gas. This equation of state has a critical point where both $\partial p/\partial V = 0$ and $\partial^2 p/\partial V^2 = 0$, given by

$$RT_c = \frac{8a}{27b}, \quad p_c = \frac{a}{27b^2} \text{ and } V_c = 3b. \quad (2)$$

Because of the dependence on the material parameters a and b , these quantities differ from gas to gas. However, when p , T , and V are expressed in terms of the critical values, the material constants disappear. With $\tilde{p} = p/P_c$, $\tilde{V} = V/V_c$, and $\tilde{T} = T/T_c$ the reduced quantities, the van der Waals equation of state

becomes

$$(\tilde{p} + 3/\tilde{V}^2)(3\tilde{V} - 1) = 8\tilde{T}. \quad (3)$$

Interestingly, this mapping between states of different gases remains useful even when the gases do not follow the predictions from van der Waals theory, for example, near the critical point and in the liquid-gas coexistence region (Stanley, 1971; Binney et al., 1992).

Universality in thermodynamic systems is often characterized quantitatively by the exponents in the power laws with which quantities, such as the specific heats, susceptibilities, and spatial or temporal correlation functions, diverge near a critical point (if the exponent vanishes, then there can be logarithmic variations or discontinuities). The ideal behavior in the thermodynamic limit is often clouded by corrections because of the finite size of the sample, and these very often show power law dependencies too. The search for universality in other systems and situations is, hence, often accompanied by investigations of scaling laws and comparisons of exponents.

The success of universality considerations in thermodynamics has triggered many investigations in nonlinear dynamical systems. Universality arguments can help to link behavior in one-dimensional maps, in chemical reactions, in electrical circuits, or in hydrodynamic systems, for instance. Here are some situations where universality and scaling appear in nonlinear systems.

Period-doubling cascade. Grossmann & Thomae (1977), Feigenbaum (1978), and Coullet & Tresser (1978) noted that the sequence of parameters λ_n in quadratic maps, like $x_{i+1} = \lambda_n(1 - 2x_i^2)$ where bifurcations from orbits of period 2^n to 2^{n+1} occur, that is, $\lambda_1 = 0.70716$, $\lambda_2 = 0.80953$, $\lambda_3 = 0.83112$, $\lambda_4 = 0.83574$, etc., form a geometric sequence, $\lambda_n = \lambda_\infty - a\delta^{-n}$ (a is a constant). The ratio

$$\delta = \frac{\lambda_n - \lambda_{n-1}}{\lambda_{n+1} - \lambda_n} \quad (4)$$

converges to a value

$$\delta = 4.669201609 \dots \quad (5)$$

This values appears for all maps with a single quadratic maximum and negative Schwartzian derivative ($f'''/f' - (\frac{3}{2})(f''/f')^2 < 0$), as a renormalization of the map due to Cvitanovic (1984), Feigenbaum (1979), Coulet & Tresser (1978), and Lanford (1982) shows. It also appears in higher-dimensional dissipative maps, in continuous differential equations, and even in partial differential equations. Experimental evidence was first found in experiments on thermal convection (Libchaber & Maurer, 1980) and in acoustical, electrical, chemical, and many other cases since. Examples are given in Schuster (1988) and Cvitanovic (1984).

Further universal scaling laws have been established for period n -tupling, for period doubling with other forms of the maximum, for the scaling of the splitting of iterates in period doubling, for the amplitudes of higher harmonics in Fourier spectra, and for the influence of noise on period-doubling bifurcations (Cvitanovic, 1984; Schuster, 1988). Period-doubling in conservative systems has different scaling exponents (MacKay & Meiss, 1987).

Other situations with universal scaling laws arise in the case of intermittency (saddle-node bifurcations) and near the break-up of tori in conservative systems (Cvitanovic, 1984; Schuster, 1988).

Pattern formation. In many pattern forming systems, the equation for the amplitude of the pattern is of Ginzburg–Landau type, with the interactions dictated by continuous and discrete symmetries of the system (Golubitsky & Schaeffer, 1985; Golubitsky et al., 1988). A simple example for a system with a real amplitude A and invariance under $A \rightarrow -A$ is

$$\partial_t A = \varepsilon A - A^3 + \Delta A, \quad (6)$$

If the control parameter ε is negative, there is no pattern. For positive ε the amplitude increases like $\varepsilon^{1/2}$. This behavior is widely observed (Cross & Hohenberg, 1993).

Singularity formation. The final stages during the formation of singularities often show asymptotic scaling behavior. For instance, two gravitating bodies starting at rest will collide with distance vanishing like $t^{2/3}$ and velocities diverging like $t^{-1/3}$. The formation of the pinching off of a cylindrical column of liquid is an example of a process that is universal not only in its scaling behavior but also in the prefactors. The formation of the pinch is due to surface tension and is counteracted by viscous effects. From the relevant material parameters surface tension γ (of dimension kg/s^2), viscosity η (kg/(m s)), and density ρ (kg/m^3), one can form a scale of length $l_p = \eta/(\rho\gamma)$ and one of time $t_p = \eta^3/(\gamma^2\rho)$. The behavior of an axisymmetric column is universal in the sense that the minimal diameter $d_{\min}(t)$ and the maximal velocity $v_{\max}(t)$ at a time t before pinch off are given by (Eggers, 1993)

$$\frac{d_{\min}(t)}{l_p} = 0.0608 \left(\frac{t}{t_p} \right),$$

$$\frac{v_{\max}(t)}{l_p/t_p} = 3.07 \left(\frac{t}{t_p} \right)^{-1/2}. \quad (7)$$

Random matrix theories. The Hamiltonian operator that describes a given quantum system has a specific form that may be poorly known, as in the case of impurities in a solid or the interactions between nucleons in an atomic nucleus, but it certainly is not arbitrary or random. Nevertheless, for very many systems, the statistical properties of eigenvectors or the statistics of neighboring eigenvalues behave in a universal way that does not depend on the specific system anymore. When rescaled by the mean distance, neighboring energy eigenvalues of hydrogen in strong magnetic fields, electrons in quantum dots, scattering resonances in nuclei such as ^{26}Al , resonance frequencies in microwave resonators, and vibrating quartz blocks can all show the same spacing distribution (Stöckmann, 1999). The only requirement is that the systems are disordered or classically chaotic. The specific form of the distributions then depends on the global symmetry properties of the Hamiltonian, that is, on whether it is real symmetric, complex Hermitian, or symplectic (Guhr et al., 1998; Stöckmann, 1999). System-specific properties appear on much larger scales of separation between eigenvalues; they can be understood within semiclassical periodic orbit theory.

Universality in turbulence. Lewis Fry Richardson described a turbulent flow as a hierarchical arrangement of vortices of different sizes that appear and disappear in an unpredictable fashion. The famous scaling laws of Kolmogorov, Obhukov, Weizsäcker, and Onsager hold that in homogeneous, isotropic turbulence, the square of the velocity difference between two points a distance r apart scales like $(\varepsilon r)^{2/3}$, where ε is now the energy dissipation (Frisch, 1995). The expectation is that this is independent of the precise mechanism of stirring, as long as it is confined to large scales and becomes exact as the Reynolds number of the flow approaches infinity. Turbulent fluctuations behind grids in wind or water tunnels or in turbulent jets support this observation.

V

VAN DER POL EQUATION

In 1926, Balthasar van der Pol derived the equation (now named after him) to describe self-sustained oscillations in a triode circuit. To solve the equation, he developed a method that is based on the separation of fast and slow time dependencies and on averaging, an idea that provides the basis of various analytic approaches to nonlinear problems (van der Pol, 1926).

In dimensionless variables, the van der Pol (VDP) equation reads

$$\frac{d^2x}{dt^2} - \mu(1 - x^2)\frac{dx}{dt} + x = 0. \quad (1)$$

The variable x represents the triode plate voltage in the oscillating circuit, and the frequency of the circuit is normalized to 1 by the appropriate change of the time scale. The parameter $\mu > 0$ gives the growth rate of small linear oscillatory perturbations, and the nonlinear term, approximating the nonlinear current-voltage characteristic of the triode, is normalized by scaling x . Physically, the VDP equation describes growth and saturation of oscillatory perturbations with eventual onset of periodic self-sustained oscillations. With a change of variables $x = dy/dr$, the VDP equation transforms to the Rayleigh equation

$$\frac{d^2y}{dr^2} - \mu \left[1 - \frac{1}{3} \left(\frac{dy}{dr} \right)^2 \right] \frac{dy}{dr} + y = 0.$$

In the case of weak instability and nonlinearity ($\mu \ll 1$), the VDP equation can be treated analytically. Here the oscillations are nearly sinusoidal with slowly (on the time scale of order $1/\mu$) varying amplitude and phase. This key observation constitutes the essence of the method of averaging developed by van der Pol.

The first step in the solution is a transformation from $(x, \dot{x})$ to new variables: the amplitudes A, B ; thus,

$$\begin{aligned} x(t) &= A(t) \cos t + B(t) \sin t, \\ \dot{x}(t) &= -A(t) \sin t + B(t) \cos t. \end{aligned} \quad (2)$$

In these variables, Equation (1) reads

$$\begin{aligned} \frac{dA}{dt} &= -\mu \dot{x}(1 - x^2) \sin t, \\ \frac{dB}{dt} &= \mu \dot{x}(1 - x^2) \cos t, \end{aligned} \quad (3)$$

where $\dot{x}, x$ on the right-hand side are to be expressed through A, B . One can see that the time variations of A, B are slow, and the major contribution to them is given by non-oscillating terms on the right-hand side of (3). Keeping only the non-oscillating terms is equivalent to averaging over the oscillation period 2π , and under the averaging procedure, the slowly varying amplitudes $A(t)$ and $B(t)$ are considered as constants. Having performed the averaging, van der Pol obtained the approximate equations in the form

$$\begin{aligned} \frac{dA}{dt} &= \frac{\mu}{2} A \left(1 - \frac{A^2 + B^2}{4} \right), \\ \frac{dB}{dt} &= \frac{\mu}{2} B \left(1 - \frac{A^2 + B^2}{4} \right). \end{aligned} \quad (4)$$

This equation can be readily solved by means of a transformation to the slow amplitude and phase $A = R \cos \phi$, $B = R \sin \phi$:

$$\frac{dR}{dt} = \frac{\mu}{2} R \left(1 - \frac{R^2}{4} \right), \quad \frac{d\phi}{dt} = 0.$$

For any initial condition $R \neq 0$, the stationary amplitude $R_0 = 2$ is established as $t \rightarrow \infty$. In the original variables of Equation (1), the corresponding periodic solution reads $x(t) = 2 \cos(t - \phi)$ (see Figure 1). In terms of the dynamical systems theory, the van der Pol equation (1) possesses a limit cycle; for small μ , the cycle is approximately circular with radius 2. Physically, it corresponds to periodic weakly nonlinear, self-sustained oscillations.

The solution of the VDP equation can be treated analytically also in the limiting case $\mu \gg 1$, when the equation describes relaxation oscillations. Introducing new time $\tau = t/\mu$, we can rewrite Equation (1) as a

Figure 1. A solution of the van der Pol equation for $\mu = 0.1$. (a) The time dependence of x . (b) The limit cycle on the phase plane ($x, dx/dt$) attracts other trajectories; its form for this small value of μ is nearly circular.

system

$$\mu^{-2} \frac{dx}{d\tau} = -y + x - \frac{x^3}{3}, \quad (5)$$

$$\frac{dy}{d\tau} = x. \quad (6)$$

This system has a small parameter μ^{-2} at the derivative, and it belongs to the class of singularly perturbed equations. All motions in the phase space (x, y) are divided into fast motions, when variable x jumps with the rate $\sim \mu^2$ while variable y remains nearly constant, and slow motions, when both variables x and y vary with rates of ~ 1 . The slow motions are restricted to the slow manifold, where the right-hand side of Equation (5) vanishes (the curve $y = x - x^3/3$ shown as a dotted line in Figure 2b). More precisely, they are restricted to the stable branches of the curve, where $d(x - x^3/3)/dx < 0$. The direction of motion on these stable branches is determined by Equation (6) and is depicted in Figure 2b by arrows. When the phase point moving along a stable branch arrives at its border, it jumps to the other branch. Thus, the limit cycle consists of two pieces of slow motion connected by two pieces of fast motion (solid line in Figure 2b).

The VDP equation serves as a prototype for different dynamical models with a limit cycle. For example, an equation with a more complex nonlinearity and $\mu > 0$,

$$\frac{d^2x}{dt^2} - \mu(-1 + x^2 - \beta x^4) \frac{dx}{dt} + x = 0,$$

describes the so-called “hard excitation” of self-sustained oscillations. (This equation was derived by van der Pol and Appleton for the description of a triode generator, whose operating point is shifted from the inflection point of the current-voltage characteristics of

Figure 2. A solution of the van der Pol equation for $\mu = 20$. (a) The time dependence of x . (b) The limit cycle on the phase plane (x, y) consists of pieces of the slow manifold (shown with a dotted line) and fast jumps of x .

the triode.) In this case, the averaging method above described leads to the following amplitude equation:

$$\frac{dR}{dt} = \frac{\mu}{2} R \left(-1 + \frac{R^2}{4} - \beta \frac{R^4}{8} \right), \quad \frac{d\phi}{dt} = 0.$$

For $\mu > 0$ and $0 < \beta < \frac{1}{8}$, this equation possesses coexisting stable steady state $R = 0$, an unstable limit cycle at $R_{un} = \beta^{-1/2}(1 - \sqrt{1 - 8\beta})^{1/2}$, and a stable limit cycle at $R_{st} = \beta^{-1/2}(1 + \sqrt{1 - 8\beta})^{1/2}$. The basin of attraction of the stable limit cycle is $R > R_{un}$, while the circle $R < R_{un}$ is the basin of the stable fixed point. For the triode generator this means that self-sustained oscillations cannot develop from small fluctuations, but appear only if a relatively large (larger than R_{un}) perturbation is applied.

Another generalization of the van der Pol equation is often called the van der Pol–Duffing oscillator:

$$\frac{d^2x}{dt^2} - \mu(1 - x^2) \frac{dx}{dt} + x + \gamma x^3 = 0. \quad (7)$$

This model combines the dissipative nonlinearity of the van der Pol equation (term proportional to μ) with the conservative nonlinearity of the Duffing equation (term proportional to γ). For $\mu \ll 1$ and $\gamma \ll 1$, the equations for the slowly varying amplitude and phase can be obtained by the method of averaging as

$$\frac{dR}{dt} = \frac{\mu}{2} R \left(1 - \frac{R^2}{4} \right), \quad \frac{d\phi}{dt} = \frac{3\gamma}{4} R^2.$$

The difference to the van der Pol case is in the phase dynamics. Now the oscillations are non-isochronous, because the dynamics of the slow phase depends on the amplitude. In particular, the frequency of the self-sustained oscillations differs from the frequency of linear oscillations by 3γ . In the VDP equation (1), such a frequency shift appears only in the second approximation (by taking into account the terms $\sim \mu^2$).

Another model related to Equation (1) is the Bonhoeffer–van der Pol (BVDP) oscillator, with equations

$$\begin{aligned}\frac{dx}{dt} &= -y + x - \frac{x^3}{3} + I_0, \\ \frac{dy}{dt} &= c(x + a - by).\end{aligned}$$

Writing this system as one second-order equation, one gets a model similar to Equation (7), but with additional terms; thus,

$$\begin{aligned}\frac{d^2x}{dt^2} - (1 - bc - x^2)\frac{dx}{dt} + c(1 - b)x \\ + \frac{bc}{3}x^3 + c(a - bI_0) = 0.\end{aligned}\quad (8)$$

In the case $b = I_0 = 0$, the BVDP model reduces to the FitzHugh–Nagumo model of neuron spiking. Depending on the parameters, both these models demonstrate self-sustained oscillations, excitability (a stable steady state that responds to a finite perturbation by generating a spike), or bistability.

A periodically forced VDP equation,

$$\frac{d^2x}{dt^2} - \mu(1 - x^2)\frac{dx}{dt} + \omega_0^2x = E \sin \omega t,$$

displays the phenomenon of frequency locking. For ω close to the natural frequency of the autonomous system ω_0 , the forced systems starts to oscillate with the frequency of the forcing term or becomes entrained. Entrainment occurs even for relatively small E , especially when $\mu \gg 1$. For large E , the forced VDP equation can demonstrate chaotic regimes.

VIRIAL THEOREM

First established by Rudolf Clausius in 1870, the virial theorem relates the average potential energy $\langle V \rangle$ to the average kinetic energy $\langle T \rangle$ of a system of particles. The particles can have arbitrary potential interactions, and the theorem holds both in classical and quantum mechanics.

For a single classical nonrelativistic particle, the theorem can be derived as a consequence of Newton’s second law: $\mathbf{F} = m d^2\mathbf{x}/dt^2$. Thus,

$$\frac{d(m\mathbf{x} \cdot d\mathbf{x}/dt)}{dt} = \mathbf{x} \cdot \mathbf{F} + m \left(\frac{d\mathbf{x}}{dt} \right) \cdot \left(\frac{d\mathbf{x}}{dt} \right), \quad (1)$$

which in terms of the momentum $\mathbf{p} = m(d\mathbf{x}/dt)$ and the kinetic energy $T = m(d\mathbf{x}/dt)^2/2$ reads

$$-\mathbf{x} \cdot \mathbf{F} = -\frac{d(\mathbf{x} \cdot \mathbf{p})}{dt} + 2T. \quad (2)$$

In taking the average over time, the first term on the right-hand side of the equation does not contribute; thus, one obtains

$$-\langle \frac{1}{2} \mathbf{x} \cdot \mathbf{F} \rangle_{av} = \langle T \rangle_{av}, \quad (3)$$

which is the classical virial theorem. The expression on the left-hand side of this equation (called the virial by Clausius) is a measure of the net attractiveness of a system.

In the special case when the force is derivable from a potential $\mathbf{F} = -\nabla V$ and the potential varies as the n th power of the distance to the origin $V = C|\mathbf{x}|^n$, the term $\mathbf{x} \cdot \mathbf{F} = -nV$, and the virial theorem reduces to

$$n\langle V \rangle_{av} = 2\langle T \rangle_{av}. \quad (4)$$

The theorem can also be obtained from a variational derivation.

Applications

- For the harmonic oscillator, $V(\mathbf{x}) = \frac{1}{2}m\omega^2|\mathbf{x}|^2$ then $n = 2$ and $E \equiv \langle V \rangle + \langle T \rangle = 2\langle T \rangle = 2\langle V \rangle$.
- For a bouncing ball, $V(\mathbf{x}) = mg|\mathbf{x}|$ and $n = 1$, then $E = 3\langle T \rangle = 3/2\langle V \rangle$.
- If the forces vary inversely as the square of the distance (as in atomic and planetary systems), then $V(\mathbf{x}) = e^2/|\mathbf{x}|$ and $n = -1$. The average kinetic energy is then numerically equal to the total energy $E = -\langle T \rangle$ but of opposite sign.
- In astrophysics, the virial theorem is a valuable tool for studying static, non-evolving (relaxed) systems such as stars (systems of gas particles), gas clouds, star clusters, galaxies, and galaxy clusters. This theorem can be used to estimate the mass of a given system since for the gravitational case $\langle T \rangle = -\frac{1}{2}\langle V \rangle$ and

$$\frac{1}{2}M_{\text{tot}} \left\langle \frac{d\mathbf{x}}{dt} \right\rangle^2 = +\frac{1}{4} \frac{GM_{\text{tot}}^2}{\langle R_{\text{tot}} \rangle}.$$

Thus, the virial mass of the system can be estimated as

$$M_{\text{tot}} \approx 2 \frac{\langle R_{\text{tot}} \rangle \langle d\mathbf{x}/dt \rangle^2}{G}.$$

- Another application of this theorem is in the classical calculation of the state equation of gases. The system considered is that of a large number N of particles with coordinates $\mathbf{x}_i$ acted on by external and internal forces $\mathbf{F}_i = \mathbf{F}_{i,\text{ext}} + \mathbf{F}_{i,\text{int}}$ and confined within a box of volume $\mathcal{V}$. As the contribution from the external forces can be related to the pressure of the gas on the walls of the box, the virial theorem takes the form

$$P\mathcal{V} = Nk_B T + \frac{1}{3} \left\langle \sum_i^N \mathbf{x}_i \cdot \mathbf{F}_{i,\text{int}} \right\rangle_{\text{av}},$$

where k_B is the Boltzmann constant. This was the application originally considered by Clausius.

- The virial theorem can be extended to a quantum system described by the linear dimensionless Schrödinger equation

$$i\psi_t = -\Delta\psi + V(\mathbf{x})\psi.$$

In this case, $2T_m = nV_m$, where T_m and V_m are the kinetic and potential energy of the m th eigenstate, respectively.

- The virial theorem can also be applied to the study of the solitary waves. As an illustration, consider the one-dimensional nonlinear Schrödinger (NLS) equation

$$iu_t + u_{xx} + 2(u^*u)u = 0, \quad (5)$$

which has solitary wave solutions that preserve their shape after collision with other solitary waves. The general form of a solitary wave is

$$u(x, t) = a \exp i \left[\frac{v_e}{2} x + \left(a^2 - \left(\frac{v_e}{2} \right)^2 \right) t - \phi_0 \right] \times \text{sech} [a(x - v_e t - x_0)], \quad (6)$$

where a is the wave amplitude and v_e the envelope velocity, while ϕ_0 and x_0 are the initial phase and position.

One of the infinite conservation laws associated to (5) is the energy

$$E = \int u_x^* u_x dx + \int -(u^* u)^2 dx,$$

where the first term is the kinetic energy (T) and the second term is the potential energy (V).

The NLS equation is derived from the Lagrangian density $\mathcal{L} = \frac{1}{2}(u u_t^* - u_t u^*) + u_x^* u_x - (u^* u)^2$ and the corresponding action is $\mathcal{S} = \int dt dx \mathcal{L}$. Consider a stationary localized solution $u = \exp(i\mathcal{E}t) u(x)$, which is the case of solution (6) with $v_e = 0$ and

$\Omega = a^2$. As the Lagrangian density is static, we can apply a dilation transformation to get the global condition $\int |u_x|^2 dx = \int (\Omega |u|^2 - |u|^4) dx$. From Equation (5), $\int (\Omega |u|^2 + |u_x|^2 - 2|u|^4) dx = 0$, which in turn implies that $\int |u_x|^2 dx = \frac{1}{2} \int |u|^4 dx$. Thus the total energy is $E = -T = \frac{1}{2}V$, and in the case of the stationary soliton, $E = -2a^3/3$.

Thus, the virial theorem provides nontrivial relations between quantities of physical interest, which can be used to test the accuracy of numerical simulations and to find variational solutions.

VISIOMETRICS

With the advent of robust and rapid sensing devices and increasing computer speeds, memories and transfer rates, the technology for observation, measurement, and computer simulation of nonlinear processes in physical and biological systems has improved rapidly, allowing massive experimental and simulated data sets to be produced. In order to gain physical insight into the evolving phenomena and construct reduced mathematical models, the mathematical essences in this sea of data need to be determined.

This can be accomplished through the process of visiometrics, which involves visualization, projection, identification and classification, extraction, tracking, quantification, and juxtaposition of evolving amorphous coherent structures and statistical backgrounds in massive multidimensional data sets. The goal is to produce cogent images and specific, parameter-scaled (normalized) graphs for intuitive understanding and mathematical analyses (Bitz & Zabusky, 1990; Zabusky et al., 1993; Feher & Zabusky, 1996; Fernandez et al., 1996; Zabusky, 1999).

Consider the process of dealing with evolving simulation data. Most simulations use continuum partial or integro-differential equations or discrete particle descriptions and produce numerous fields, particle locations, and trajectories. (In hybrid codes both are present.) Examples of continuum fields mainly from the compressible Euler equations of fluid motion are presented here. For particle data (e.g., from Monte Carlo

or plasma simulations), appropriate local averages can be used to convert to continuum quantities.

In fluid flows, we deal with scalars such as density, pressure, and temperature, vectors such as velocity $\mathbf{u}$ and vorticity $\boldsymbol{\omega}$, and tensors such as the rate of strain tensor $\nabla \mathbf{u}$. Very thin high-gradient regions such as shock waves and diffusing interfacial transition layers (ITLs) (Zabusky et al., 2003) between species with different properties may be embedded in the flows. To quantify the ITLs, we may extract a medial axis (i.e., some center line) or surface, so we can determine tangents and normals to these curves in two-dimensions (2-d) and surfaces (in 3-d), respectively. In 3-d, the curvatures of these medial surfaces may be important tensors. The visiometrics operations of visualization, projection, identification and classification, extraction, tracking, quantification, and juxtaposition are each considered below.

Visualization: Numerical fields are displayed in a variety of 2-d and 3-d images. The data are first pre-processed or filtered to make them more accessible visually. High wave number incoherent modes are removed with a filter (e.g., the wavelet process of Farge et al., 2001). The choice of appropriate color maps (palettes) (Farge, 2000) is a nontrivial operation. Farge (1992) represented the vorticity scalar with a grayscale format for lower magnitudes, a yellow intermediate contour for the region near zero, and a few graded colors for the higher magnitudes. In DAVID (see http://www.caip.rutgers.edu/~nzabusky/vizlab_cfd/david/david.html), an interactive color domain system has been developed with colors chosen, for example, with hue, saturation, and value (HSV), and with optional black/white grading superimposed in each color domain. The user sees the image automatically colored as the color map is modified. Simultaneously, at each color transition, the numerical value of the function and between neighboring color transitions, the integrated content, and the corresponding underlying pixel-area of the image are seen. (This gives the user a qualitative feeling about the magnitudes of the objects that the color renders.)

Standard visualization techniques include continuous or discrete contour maps in 2-d; volume rendering a function in 3-d as it would appear when radiating or reflecting light from various sources (Upson & Keeler, 1988); and displaying isosurfaces (contours) from connected polygons that bound regions of functions extracted by thresholding (Lorensen & Cline, 1987). There are many excellent computer vision and scientific visualization contemporary texts in the literature (both web and printed).

Projection: A general process produces abstract images and graphical information in lower dimensions, for example, the projection to 2-d from 3-d by integration with respect to a kernel. If it is a planar delta function, one extracts 2-d surfaces or curves from 3-d or 2-d spatial data, respectively. Also, integration of an appropri-

ately weighted field variable transverse to some initial axis or flow direction (like that behind a planar shock in a shock tube) will produce a space-time diagram from a 2d+1 data set (see color plate section; Figure 2 of Hawley & Zabusky, 1989; see also Zabusky, 1999).

Identification and classification: The geometry, topology, content, moments, and distribution functions of an extracted region are examined. Are the domains in 3-d layer-like or tube-like? Are the tube-like domains right- or left- handed helices?

Extraction and setting of thresholds: Complex data sets may have a hierarchy of embedded coherent structures in a sea of incoherent very small-scale structures. Farge and colleagues (Farge et al., 2001) have applied a threshold prescription to wavelet amplitude coefficients and have developed high-compression techniques to systematically extract coherent vortex objects. Samtaney and Zabusky (2000) have examined the extraction of shocks and species ITLs in 2-d. For ITLs, one looks at absolute values of gradients and Laplacians of the density, temperature, and so on. Various heuristic and analytical methodologies have been presented by Villasenor & Vincent (1992), Melander & Hussain (1994), Jeong & Hussain (1995), Kida & Miura (1998), and Miura (2002). The results of Melander, Jeong, and Hussain are particularly noteworthy.

Tracking: Structures in space-time that have been extracted and identified are followed. One must allow for objects to collide and amalgamate, split, be created, and disappear (Samtanay et al., 1994). Post et al. (2002) and colleagues (e.g., Vrolijk et al., 2003) have carried this work further. With this information, we may be able to formulate kinematic and dynamical models.

Quantification: Graphs of projected and tracked structures are plotted and underlying physical, mathematical, and numerical parameters are varied. In the vicinity of extrema (e.g., magnitude of vorticity $\boldsymbol{\omega}$), second- and third-order moments are useful (e.g., ellipsoids in 3-d). Distribution functions of one or more variables are evaluated, and statistical characterizations of incoherent domains, after structures have been extracted, are examined.

Juxtaposition: These comparisons are of similar or different functions at the same or different times from simulations of the same or linked mathematical models in a relevant domain of parameters. Coherent structures of different functions (e.g., density or vorticity) and their quantifications with runs from different resolutions (validation) and parameters (scaling physical behavior) are compared. One often has to remove a background translation or rotation.

As nonlinear phenomena are simulated at increasingly high resolution and for longer times on adaptive meshes across parallel processors, the validity of results becomes an important issue. Numerical errors accumulate from round-off, truncation (e.g., higher-order and nonlinear dissipative and dispersive regularizations),

spatially and temporally adjusting meshes, and ad-hoc filters. The visiometric process will help find these defects and provide a more rigorous basis for model building and prediction. Visiometrics will also produce new art forms (Zabusky, 2000).

VOLCANOS

See **Geomorphology and tectonics**

VOLTERRA SERIES AND OPERATORS

In addition to playing an important role in the development of theoretical biology, the Italian mathematician Vito Volterra (1860–1940) also strongly influenced the development of modern calculus. We deal here with the Volterra functional series (VFS) and associated Volterra differential operators (VDO) which provide a consistent mathematical framework for stating material properties in nonlinear wave propagation systems, for example, in nonlinear optics (Censor & Melamed, 2002; Censor, 2000; Sonnenschein & Censor, 1998). For simplicity, the present introduction is restricted to the temporal domain, adequate for time signals. Waves require a spatiotemporal domain.

Linear Systems

Modeling of physical systems requires material (or constitutive) relations. In electromagnetics, we have relations like $D = \epsilon E$, $B = \mu H$; in acoustics, the compressibility (relation of pressure to volume) is needed; in elastodynamics, we include Hooke's law (relation of stress to strain). Here $D = \epsilon E$ and its nonlinear extensions are treated as prototypes.

Materials are dispersive, depending (in the restricted sense of temporal dispersion discussed here) on frequency f . Consider the linear case first:

$$D(\omega) = \epsilon(-i\omega)E(\omega), \quad \omega = 2\pi f, \quad (1)$$

where ω is the angular frequency, and defining $\epsilon(-i\omega)$ instead of $\epsilon(\omega)$ is convenient for subsequent applications.

The Fourier transform pair

$$\begin{aligned} F(t) &= \frac{1}{2\pi} \int_{-\infty}^{\infty} d\omega F(\omega) e^{-i\omega t}, \\ F(\omega) &= \int_{-\infty}^{\infty} dt F(t) e^{i\omega t} \end{aligned} \quad (2)$$

relates the spectral and temporal domains. We use the same symbol F , although $F(t)$ and $F(\omega)$ are different functions. Accordingly, (1) becomes a convolution integral

$$D(t) = \int_{-\infty}^{\infty} dt_1 \varepsilon(t_1) E(t - t_1), \quad (3)$$

where $D(t)$, $\varepsilon(t)$, $E(t)$, are related to $D(\omega)$, $\varepsilon(-i\omega)$, $E(\omega)$, respectively, according to (2). Note that (3) can be viewed as an integral operation, acting on $E(t)$. Also (3) is the simplest form of a VFS.

Formally we can start with (1), transform according to (2), and note that in the integral $E(-i\omega)$ (if it can be represented or approximated by a polynomial in $-i\omega$) can be considered as a polynomial operator $\varepsilon(\partial_t)$ acting on the exponential, in which every time derivative ∂_t replaces a term $-i\omega$ in $\varepsilon(-i\omega)$. Note that $\varepsilon(t)$ and $\varepsilon(\partial_t)$ are different functions, but $\varepsilon(-i\omega)$ and $\varepsilon(\partial_t)$ possess the same functional structure. Thus, instead of (3), we now have the VDO representation

$$D(t) = \varepsilon(\partial_t) E(t) = \varepsilon(\partial_\tau) E(\tau) \big|_{\tau \rightarrow t}. \quad (4)$$

The last expression in (4) with the instruction $\tau \rightarrow t$ is superfluous here but will be important for the nonlinear case below. The possibility of using this technique for $\varepsilon(\partial_t)$ a rational function (ratio of polynomials) is discussed elsewhere (Censor, 2001).

As a trivial example for (3) and (4), consider a harmonic signal

$$\begin{aligned} E(t) &= E_0 e^{-i\omega t}, \\ D(t) &= E_0 e^{-i\omega t} \int_{-\infty}^{\infty} dt_1 \varepsilon(t_1) e^{i\omega t_1} \\ &= \varepsilon(-i\omega) E_0 e^{-i\omega t} = \varepsilon(\partial_t) E_0 e^{-i\omega t} \end{aligned} \quad (5)$$

clarifying the role of the VDO in (4).

Nonlinear Systems and the Volterra Series and Operators

In nonlinear systems, the material relations involve powers and products of fields. Can we simply replace (1) by a series involving powers of $E(\omega)$? A cursory analysis reveals that this leads to inconsistencies. Instead, we ask if (3) can be replaced by a “super convolution” and what form that should take. Indeed, the Volterra series provides a consistent mathematical answer to these questions.

It is given by

$$\begin{aligned} D(t) &= \sum_m D^{(m)}(t), \\ D^{(m)}(t) &= \int_{-\infty}^{\infty} dt_1 \dots \int_{-\infty}^{\infty} dt_m \\ &\quad \times \varepsilon^{(m)}(t_1, \dots, t_m) E(t - t_1) \dots E(t - t_m). \end{aligned} \quad (6)$$

Typically, the VFS (6) contains the products of fields expected for nonlinear systems, combined with the convolution structure (3). Various orders of nonlinear interaction are indicated by m .

Theoretically, all the orders co-exist (in practice, the series will have to be truncated within some approximation), and therefore, we cannot inject a time harmonic signal as in (5). If instead, we start with a periodic signal, $E(t) = \sum_n E_n e^{-in\omega t}$ and substitute in (6), we find

$$\begin{aligned} D^{(m)}(t) &= \sum_{n_1, \dots, n_m} \varepsilon^{(m)}(-in_1\omega, \dots, -in_m\omega) \\ &\quad \times E_{n_1} \dots E_{n_m} e^{-iN\omega t} = \sum_N D_N e^{-iN\omega t}, \\ N &= n_1 + \dots + n_m, \end{aligned} \quad (7)$$

with (7) displaying the essential features of a nonlinear system, namely, the dependence on a product of amplitudes, and the creation of new frequencies as sums (including differences and harmonic multiples) of the interacting signals frequencies. In addition, (7) contains the weighting function $\varepsilon^{(m)}(-in_1\omega, \dots, -in_m\omega)$ for each interaction mode.

The extension of (4) to the nonlinear VDO is given by

$$\begin{aligned} D^{(m)}(t) &= \varepsilon^{(m)}(\partial_{t_1}, \dots, \partial_{t_m}) \\ &\quad \times E(t_1) \dots E(t_m) \big|_{t_1, \dots, t_m \rightarrow t}. \end{aligned} \quad (8)$$

In (8), the instruction $t_1, \dots, t_m \rightarrow t$ guarantees the separation of the differential operators, and finally renders both sides of the equation to become functions of t .

The VFS (6), including the convolution integral (3), is a global expression describing $D(t)$ as affected by integration times extending from $-\infty$ to ∞ . Physically, this raises questions about causality, that is, how future times can affect past events. In the full-fledged four-dimensional generalization, causality is associated with the so-called “light cone” (Bohm, 1965). It is noted that the VDO representation (4, 8) is local, with the various time variables just serving for bookkeeping of the operators, and where this representation is justified, causality problems are not invoked.

In general, the frequency constraint of (7) is obtained from the Fourier transform of (6), having the form

$$D^{(m)}(\omega) = \frac{1}{(2\pi)^{m-1}} \int_{-\infty}^{\infty} d\omega_1 \dots \int_{-\infty}^{\infty} d\omega_{m-1} \\ \times \varepsilon^{(m)}(-i\omega_1, \dots, -i\omega_m) E(\omega_1) \dots E(\omega_m), \\ \omega = \omega_1 + \dots + \omega_m. \quad (9)$$

It is noted that in (9), we have $m - 1$ integrations, one less than in (6). This tallies with the linear case where (1) and (3) involve zero and one integration, respectively. Consequently, the left- and right-hand sides of (9) are functions of ω and ω_m , respectively. The additional constraint $\omega = \omega_1 + \dots + \omega_m$ completes the equation and renders (9) self-consistent.

Summary

The modeling of nonlinear media using the VFS and VDO provides a mathematically consistent framework which includes linear media as a limiting case. The model displays the typical ingredients of nonlinear circuits and wave systems, where the nonlinear terms are proportional to the product of the amplitudes of the interacting fields, and the newly created frequencies are sums (or differences, or harmonic multiples) of the interaction frequencies, given by $\omega = \omega_1 + \dots + \omega_m$. In the quantum-mechanical context this is an expression of the conservation of energy. Not shown here is the associated wave propagation vector constraint $\mathbf{k} = \mathbf{k}_1 + \dots + \mathbf{k}_m$, which in the quantum-mechanical context expresses conservation of momentum. Schetzen (1980) is an excellent source of further reading on VFS in nonlinear systems and has many early references.

VORTEX DYNAMICS IN EXCITABLE MEDIA

Vortices in excitable media include spiral waves in two spatial dimensions and scroll waves in three spatial dimensions. They are described by reaction-diffusion systems of equations,

$$\partial_t \mathbf{u} = \mathbf{f}(\mathbf{u}) + \mathbf{D} \nabla^2 \mathbf{u} + \varepsilon \mathbf{h}, \\ \mathbf{u}, \mathbf{f}, \mathbf{h} \in \mathbb{R}^\ell, \mathbf{D} \in \mathbb{R}^{\ell \times \ell}, \ell \geq 2, \quad (1)$$

where $\mathbf{u}(\mathbf{r}, t) = (u_1, u_2, \dots)^T$, is a column-vector of the reagent concentrations, $\mathbf{f}(\mathbf{u})$ is a column vector of the reaction rates, $\mathbf{D}$ is the matrix of diffusion coefficients, $\varepsilon \mathbf{h}(\mathbf{u}, \mathbf{r}, t)$ is some small perturbation, and $\mathbf{r} \in \mathbb{R}^2$ or $\mathbb{R}^3$ is the vector of coordinates on the plane or in space.

In an unbounded two-dimensional medium with $\varepsilon \mathbf{h} = 0$, a spiral wave solution rotating with angular velocity ω has the form

$$\mathbf{u} = \mathbf{U}(\mathbf{r}, t) = \mathbf{U}[\rho(\mathbf{r}), \vartheta(\mathbf{r}) + \omega t] \\ \approx \mathbf{P}[\rho(\mathbf{r}) - \frac{\lambda}{2\pi}(\vartheta(\mathbf{r}) + \omega t)] \Big|_{\rho \rightarrow +\infty}, \quad (2)$$

where $\rho(\mathbf{r})$ and $\vartheta(\mathbf{r})$ are the polar coordinates corresponding to the cartesian coordinates $\mathbf{r}$. $\mathbf{P}(\xi; \omega, \lambda)$ is a periodic wave solution with frequency ω and spatial period λ , so the $\rho \rightarrow +\infty$ asymptotic means that isolines are approximately Archimedean spirals with pitch λ . Solutions (2) are typically possible for isolated values of ω and corresponding λ .

Note that system (1) with $\varepsilon \mathbf{h} = 0$ is invariant with respect to the Euclidean group of motions of the plane $\{\mathbf{r}\}$. Solution (2) is a relative equilibrium, meaning that the states of the wave at all moments of time are equivalent to each other up to a Euclidean motion, namely, a rotation around the origin. If (2) is a solution, then from symmetry

$$\tilde{\mathbf{U}} = \mathbf{U}(\rho(\mathbf{r} - \mathbf{R}_\odot), \vartheta(\mathbf{r} - \mathbf{R}_\odot) + \omega t - \Phi_\odot) \quad (3)$$

is another solution for any constant displacement vector $\mathbf{R}_\odot = (X_\odot, Y_\odot)^T$ and initial rotation phase $\Phi_\odot$. Thus, we have a three-dimensional manifold, parameterized by coordinates $X_\odot, Y_\odot, \Phi_\odot$, of spiral wave solutions

neutrally stable with respect to each other. By “dynamics” of the vortices, we understand any deviation of the solutions from the stationary rotation (2).

Meander

A nonstationary rotation of a spiral wave accompanied by constant change of its shape is called meander. It is convenient to describe this phenomenon in terms of the spiral tip, which can be defined as an intersection of selected isolines of two components of the nonlinear field u ,

$$\begin{aligned} u_{j_1}(X_\bullet, Y_\bullet, t) &= v_1, \quad u_{j_2}(X_\bullet, Y_\bullet, t) = v_2, \\ \Phi_\bullet &= \arg(\partial_x + i\partial_y)u_{j_3}(X_\bullet, Y_\bullet, t), \end{aligned} \tag{4}$$

$j_1 \neq j_2$, where $X_\bullet(t)$, $Y_\bullet(t)$ are the coordinates of the tip and $\Phi_\bullet(t)$ is its orientation angle. Typically, a spiral wave in a given system develops the same kind of meander pattern $X_\bullet(t)$, $Y_\bullet(t)$ independent of the initial conditions. Changes of parameters in the same system change the meander pattern, and types of patterns can be qualitatively similar in very different excitable media models.

Possible types of meander can be classified using an orbit manifold decomposition of (1) by the Euclidean group. Evolution of the shape of the wave can be described in coordinates (ξ, η) in a moving frame of reference attached to the spiral tip,

$$\begin{aligned} \partial_t \mathbf{u} &= \mathbf{D}(\partial_\xi^2 + \partial_\eta^2) \mathbf{u} + [C_1(t)\partial_\xi + C_2(t)\partial_\eta \\ &\quad + \omega(t)(\xi\partial_\eta - \eta\partial_\xi)] \mathbf{u} + \mathbf{f}(\mathbf{u}) \\ u_{j_1,2}(0, 0) &= 0, \quad \partial_\eta u_{j_3} = 0, \end{aligned} \tag{5}$$

and the movement of the tip is described by ordinary differential equations

$$\begin{aligned} \frac{d\Phi_\bullet}{dt} &= \omega(t), \\ \frac{dX_\bullet}{dt} + i\frac{dY_\bullet}{dt} &= (C_1(t) + iC_2(t))e^{i\Phi_\bullet}. \end{aligned} \tag{6}$$

Equations (5) define a dynamic system with the phase space $\{(\mathbf{u}(\xi, \eta), C_1, C_2, \omega)\}$, devoid of the Euclidean symmetry of the original system (1). Knowing the attractor in (5), one can deduce the properties of the meander patterns by integrating the ODE system (6) (see Figure 1).

Forced Drift

Another kind of deviation from (2) is drift of spirals due to perturbations $\varepsilon \mathbf{h} \neq 0$. As solutions of family (3) are neutrally stable with respect to each other, a small perturbation of a spiral wave caused by an $\varepsilon \mathbf{h}$ limited in time will die out, but it will typically result in a small change in the spiral wave coordinates $X_\odot$, $Y_\odot$ and $\Phi_\odot$.

Figure 1. Typical meander patterns. Shown are snapshots of the excitation field with pieces of preceding tip paths superimposed. (a) Stationary (rigid) rotation: equilibrium in the base system (5). (b) Classical biperiodic “flower” meander: limit cycle in the base system (5). (c) Quasi-periodic hypermeander: invariant torus in the base system (5). (d) Pseudorandom walk hypermeander: chaotic attractor in the base system (5) (only the tip path shown).

If similar perturbations are applied repeatedly with a period equal to the period of the spiral, then small shifts of $X_\odot$ and $Y_\odot$ accumulate, which is called a resonant drift. Another type of slow drift is inhomogeneity-induced drift, occurring when $\varepsilon \mathbf{h}$ depends explicitly on spatial coordinates (medium properties are slightly inhomogeneous, as in Figure 2(b)). In the first order of perturbation theory, this is equivalent to a time-dependent perturbation synchronized with the spiral rotation and is therefore resonant. A third type of drift occurs if the medium is bounded, and the boundary influence on the spiral wave is not negligible. Although a boundary is not a slight perturbation, the effects of passive (nonflux) on the spiral wave can be small and similar to that of small spatial inhomogeneity (Figure 2(c)). Other kinds of perturbations breaking the Euclidean symmetry of (1) can also cause drift.

Being a first-order effect, the slow drift of a spiral due to small forces of different types obeys a superposition principle. It leads to motion equations

$$\begin{aligned} \partial_t(X_\odot + iY_\odot) &= C(X_\odot, Y_\odot) + v(X_\odot, Y_\odot)e^{i\Theta}, \\ \partial_t\Theta &= \Omega(t) - \omega(X_\odot, Y_\odot), \end{aligned} \tag{7}$$

where $C(X_\odot, Y_\odot)$ is the velocity of the inhomogeneity and boundary induced drift, $v(X_\odot, Y_\odot)$ is the velocity of the resonant drift, Θ is the phase difference between the spiral and the resonant forcing, $\Omega(t)$ is the

Figure 2. Different drifts of spiral waves. Shown are snapshots of the excitation field with pieces of preceding tip paths superimposed. The right half of the medium is slightly “stronger” than the left half; (a)–(c) are consecutive stages of the same numeric experiment. (a) Two close oppositely charged spirals attract with each other and form a pair drifting in SE direction. (b) The spirals have reached the inhomogeneity and are being driven apart by it. (c) The spirals have reached the medium boundary and now drift along it. (d) In a bigger medium: the right spiral has subdued the left spiral into an induced drift.

perturbation frequency, and $\omega(X_{\odot}, Y_{\odot})$ is the own spiral angular frequency possibly depending on the current spiral location.

These are motion equations for rigidly rotating spirals, and $X_{\odot}$ and $Y_{\odot}$ are sliding period averages of $X_{\bullet}$, $Y_{\bullet}$. Dynamics of forced meandering spirals are more complicated because of possible resonances.

Spiral Waves as Particles

Motion equations (7) are obtained by summation of the effects of elementary perturbations of different modalities localized in different sites and occurring at different moments of time, onto the spiral’s location and phase. These elementary responses are described by response functions, which are critical eigenfunctions of the adjoint linearized operator. An interesting property of the response function is their localization in the vicinity of the spiral core (see Figure 3). The spiral will only drift if the perturbation is applied not too far from its core.

A paradox is thus created. Although a spiral wave appears as a significantly nonlocal process, involving in its rhythm all of the excitable medium, it behaves as a localized, particle-like object in its response to perturbations.

Figure 3. A spiral wave solution (a) and its temporal (b) and spatial (c,d) response functions, as density plots. Monotone gray periphery on (b–d) corresponds to zero. Thus the spiral wave is a non-local process, but its response functions are well localized.

A spatial response function, defining the proportionality between drift velocity and inhomogeneity magnitude, typically has scalar (drift along the parameter gradient or toward the boundary) and pseudo-scalar (across the parameter gradient or along the boundary) components. The sign of the latter depends on the direction of the spiral rotation.

Bending and Twisting of Scroll Waves

As a scroll wave is a three-dimensional analogue of a spiral wave, all comments about spiral wave dynamics remain valid for the scrolls, but there are new aspects arising from the third dimension. The simplest 3-d vortex is the straight scroll wave, a spiral wave continued unchanged in the third dimension. The spiral tip, a point in the plane, becomes the edge of the scroll, a line in space, and the spiral core, a circle in the plane, becomes the scroll filament, a tube. The term *filament* also sometimes denotes the center line of the tube filament.

More interesting regimes are scrolls with bent filaments (Figure 4(a)), and with rotation phase varying along the filament (twisted scrolls, as in Figure 4(b)). Both bending and twist of scrolls are factors of their dynamics. A vortex ring will collapse or expand and, at the same time, drift along its symmetry axis, and twisted vortex will usually spread the twist evenly along its filament or, if possible, untwist.

The asymptotic motion equation for the scroll waves can be derived using response functions. If the twist is

Figure 4. Scroll waves. (a) Scroll with a curved filament. (b) Twisted scroll with straight filament. (c) Scroll with a knotted filament. (d) “Turbulent regime”: many scrolls developed from one via negative filament tension multiplication mechanism. On panels (c) and (d), part of the wavefronts is cut out, to make the filaments (white lines) visible.

not too strong, then the dynamics of the scroll due to bending and due to twist are decoupled. The motion equation of the filament is

$$\partial_t \mathbf{R}_f = b_2 \partial_s^2 \mathbf{R}_f + c_3 [\partial_s \mathbf{R}_f \times \partial_s^2 \mathbf{R}_f], \quad (8)$$

where $\mathbf{R}_f = \mathbf{R}_f(p, t) \in \mathbb{R}^3$ is the position of the filament as function of a length parameter p and time, and ∂_s is arclength differentiation, $\partial_s \equiv |\partial_p \mathbf{R}_f|^{-1} \partial_p$. At $b_2 = 0$, Equation (8) is completely integrable; in particular, the total length of the filament is conserved. Otherwise, the total filament length decreases if $b_2 > 0$ and increases if $b_2 < 0$, and in the latter case, a straight filament is unstable.

If twist is high, it changes the filament tension and may make it negative. This causes an instability of the straight filament shape, leading to “sproing”: a sudden transition from a strongly twisted scroll with straight filament to a less twisted scroll with a helical filament.

Competition and Interaction (*Divide et impera*)

Normally, two colliding excitation waves annihilate each other. Thus, if there are many periodic sources of waves (e.g., vortices), then the medium splits into domains, or regions of influence, each domain receiving waves from its source. The domains are separated by shock structures where the waves collide (see Figure 2(a–c)).

The domain boundaries work like non-flux boundaries. Thus, two spiral waves can interact with each other (cause each other’s drift and frequency shift), whereas each of them actually interacts with the boundary between their domains. Such interaction between spirals may lead to the formation of linked pairs (see Figure 2(a)).

Different scroll filaments or different parts of the same filament can also interact with each other. If this interaction is repulsive, it may compensate positive tension normally causing closed filaments to contract and collapse, leading to stable “particle-like” 3-d scrolls with compact filaments (see Figure 4(c)).

Induced Drift

If colliding waves annihilate in a ratio of one-to-one, continuity of phase applies. If two vortices have different frequencies (e.g., because of a spatial inhomogeneity of the medium), then by continuity of phase the domain boundary between them moves toward the slower vortex. When it reaches its core, the slower vortex loses its identity and turns into a dislocation in the wave field emitted by the faster vortex. This dislocation, appearing as a free end of an excitation wave, periodically rejoins from one wave to another with some overall drift depending on the frequency and direction of the incident waves (see Figure 2(d)). If the incident wave packet ceases, the dislocation can develop into a vortex again.

As a dislocation is very different from a vortex, this induced drift is an example of hard, non-perturbative dynamics.

Hard Dynamics: Births, Deaths, and Multiplication of Vortices

Another kind of hard dynamics involves complete elimination of a vortex. This may happen if the wave propagation around the vortex becomes impossible, for example, if the vortex has been driven too close to a medium boundary. Alternatively, two spiral waves with opposite topological charges may annihilate if driven too close to each other. For a scroll wave, annihilation may happen to a piece of its filament, which then appears as splitting of a scroll wave into two.

Birth of a vortex may occur as a result of a temporary local block of excitation propagation. Unless this happens near the medium boundary, this means birth of a pair of oppositely rotating spirals in the plane, or a scroll with a closed filament around the perimeter of the propagation block. The block may occur as a result of external forcing or special initial conditions, or develop as a result of an instability of an existing vortex. Such instability can underlie a chain reaction of the vortex multiplication, which may lead to a turbulence of excitation vortices—a spatiotemporal chaotic state

where generation of new vortices is balanced by their annihilation when they get close to each other due to overcrowding.

Several mechanisms of such instabilities have been identified, including those working in two or three dimensions, such as Eckhaus instability, zigzag/lateral instability or imposed mechanical movement of the medium, and those possible only in three dimensions. The latter include instability due to the negative "tension" b_2 of the vortex filament (see Figure 4(d)), or caused by spatially inhomogeneous anisotropy of the medium such as that observed heart ventricular muscle. Some of these types of instabilities may be responsible for the phenomenon of fibrillation of the heart (See **Cardiac arrhythmias**).

VORTEX DYNAMICS OF FLUIDS

The swirling and chaotic behavior of vortex-dominated fluid flows has inspired philosophers, poets, and artists from antiquity to the present, including Leonardo da Vinci, the 15th-century artist, scientist, and engineer who captured complex fluid motions as part of his applied and creative work (van Dyke, 1982; Lugt, 1983; Minahan, 1992). The traditional woodblock prints (*Ukiyo-e*) of Hiroshige and Hokusai also show spiral motion produced by a vortex and "curls" on

breaking ocean waves in various locations around Japan (Zabusky, 2000).

Vorticity is a measure of the "spin" or rotation of the fluid and is usually represented by a continuous vector variable $\omega(\mathbf{x}, t)$. Regions of flow that do not contain vorticity are called irrotational. Vorticity can be defined in two equivalent ways. First, as the curl of the velocity $\mathbf{u}$, $\omega = \nabla \times \mathbf{u}$. Second, and more geometrically, as a limit (when it is finite) of a closed circuit integral over a domain boundary D' (or equivalently the integral over domain D within boundary D') whose enclosed area $A \rightarrow 0$, or $\omega = e_{\tan} [\lim_{A \rightarrow 0} (\Gamma/A)]$ where for finite A , Γ is the circulation or line integral of velocity around the domain,

$$\Gamma = \int_{D'} \mathbf{u} \cdot d\mathbf{s} = \int_D \omega \cdot d\mathbf{A} \quad (1)$$

and $e_{\tan}$ is the tangent to the vorticity vector at the point where $A \rightarrow 0$. Note that the scalars $\frac{1}{2}\omega \cdot \omega$ (enstrophy) and $\omega \cdot \mathbf{u}$ (helicity) arise frequently in discussions of turbulence.

Leonhard Euler derived continuum mathematical equations for an ideal (non-dissipative) fluid. In the 19th century, Claude Navier, George Stokes, and others included dissipative processes for a realistic viscous fluid (Lamb, 1932; Batchelor, 1967; Kiselev et al., 1999). These equations provide models of fluids under usual (for example nonrelativistic) conditions. Asymptotic (reduced) mathematical equations, particularly those emphasizing inviscid vortex-dominated flows (Saffman, 1992) were derived in the 19th century with works of William Thomson (Lord Kelvin) and Hermann von Helmholtz, among others (See **Kelvin–Helmholtz instability**). Vortex models are used today to predict the behavior of geophysical and astrophysical fluids (Nezlin, 1993), and in engineering applications (Green, 1995).

If $\omega(\mathbf{x}, t)$ is modeled by one or more line filaments in three dimensions (3-d) on which the vorticity is concentrated, then the velocity produced by this vorticity can be calculated from a (Biot–Savart) line integral over the filaments. With this velocity, one can obtain the trajectories of points in the fluid merely by solving $d\mathbf{x}/dt = \mathbf{u}(\mathbf{x}, t)$. In 2-d planar flows, the vorticity vector has one component perpendicular to the plane, ($\omega = \partial_x v - \partial_y u$), and it may be modeled by one or more points of strength Γ_i .

With these definitions, one can prove some fundamental theorems, including the following (Kiselev et al., 1999):

- **Thomson's theorem:** In an ideal barotropic moving fluid, Γ for any closed contour does not depend on time.
- **Helmholtz's theorem:** If the particles of a liquid satisfy Thomson's theorem and form a vortex filament at some moment of time, then these particles form a vortex filament at all subsequent and previous

moments of time and the vortex tube of circulation Γ will be time invariant and constant along its length.

For 2-d, the simplicity of the kinematic description for homogeneous incompressible fluids allows for simple computer models and valuable insights into the motion of ideal fluids. For example, point circulations Γ_i are usually positive and negative constants; vortex sheets along a line described by the circulation per unit length $\gamma(s, t)$; or vorticity $\omega(\mathbf{x}, t)$ is constant in a domain (See **Contour dynamics**). (Note that for points and sheets, the equations are ill-posed mathematically, and regularization techniques must be used when computing numerically long times.) Interesting effects observed in 2-d include the merger of like-signed vortex domains if initially placed sufficiently close, binding of opposite-signed domains into “vortex projectiles” (a generic translating form whose simplest example is the dipole composed of two opposite-signed points). For vortex sheets, a linear (Kelvin–Helmholtz) stability analysis shows growth of a perturbation for all wavelengths of the disturbance. These evolve into finite-amplitude rolls with a characteristic spiral depending on their sign (see photo of an atmospheric vortex sheet on page 1 of color plate section). If one relaxes the sheet to a very thin layer then small wavelength perturbations are stabilized whereas wavelengths larger than the initial thickness remain unstable. Placing more than one harmonic perturbation on the thin layer, one observes roll-up and merger (energy cascade to large scales) as well as entropy cascade to smaller scales; that is, the process becomes turbulent. Many details are found in the references below.

In 3-d, ω may be concentrated on one or more filamentary lines or in finite area tubes, for example, the well-known vortex ring which translates at uniform speed and is unstable (Shariff & Leonard, 1992). If the ring is perturbed, this can lead to collapse and reconnection (Kida & Takaoka, 1994; Fernandez et al., 1995). In a dramatic experiment, Lim and Nickels (1992, 1995) fired a blue and red vortex ring toward each other in water and observed them interact and split into many blue-red smaller vortex ringlets.

The vorticity evolution equation is obtained if one applies the curl operation to the fluid momentum equation. This shows clearly many fundamental and interesting results on vorticity creation, modification, and dissipation. For the zero viscosity (ideal or Euler equation) limit, we have

$$\begin{aligned} \frac{\partial \omega}{\partial t} + \mathbf{u} \cdot \nabla \omega + \omega(\nabla \cdot \mathbf{u}) \\ = \omega \cdot \nabla \mathbf{u} + \rho^{-2}(\nabla \rho \times \nabla \rho). \end{aligned} \quad (2)$$

On the right-hand side the terms are: (1) vorticity “stretching” by the rate of strain tensor, which is only present in 2-d-axisymmetric and 3-d motions

and is essential for turbulence seen in 3-d; and (2) baroclinic terms, which stem from the misalignment between the gradient of density and either the gravitation vector or the gradient of pressure. Both are important in incompressible inhomogeneous multi-species fluids (e.g., the Rayleigh–Taylor instability) and the latter term is important when shock waves interact with density inhomogeneities in compressible fluids (known as the Richtmyer–Meshkov (RM) instability environment). Recently, Ghoneim and colleagues (e.g., Soteriu & Ghoneim, 1995; Reinaud et al., 2000) used a point vortex model to represent inhomogeneous fluids where Γ_i and $\nabla \rho$ vary in time and Zabusky and colleagues have quantified the vortex-accelerated vorticity deposition in the compressible RM environment (Peng et al., 2003) relevant to laser fusion and super-sonic combustion.

For real fluids with small dissipation or at high Reynolds number,

$$\text{Re} = \frac{UL}{\nu} = \frac{\text{velocity} \times \text{length}}{\text{kinematic viscosity}}, \quad (3)$$

these insights are for short times. Vorticity is generated in a thin boundary layer in the vicinity of rigid or compliant objects in the flow—for example, cylinders (Williamson, 1996), spheres, or airfoils—or within channels because of viscosity (non-slip boundaries). Note, that the larger the Reynolds number, the more “unstable” is the fluid motion and the more likely that one finds it in a turbulent state. Cogent discussions of realistic turbulent effects including vortex phenomena are given in recent books (Pope, 2000; Tsinober, 2001).

Vortices are audible. When we hear the wind howling or the crack of a whip, we are sensing vortices in action. Aeroacoustics, the branch of fluid dynamics concerned with sound generated from vortices, is being applied to noise from jet engines, sounds in music and speech, and so on.

Currently, active fields of study include separating turbulent flows into their coherent and incoherent vortex structures (thereby simplifying prediction and control of flows) (See **Visiometrics**). These studies arise in geophysics (e.g., hurricanes, the Gulf stream, and Jupiter’s red spot) and astrophysics (planetary nebulae, supernova, and galaxy collisions).

WATER WAVES

Water waves have attracted the attention of scientists for many centuries. Although much is now understood, they are a continuing source of fascination, as many aspects of their often-complicated nonlinear behavior remain to be fully elucidated. We describe first the linear theory, much of which was developed in the 19th century, before discussing the more modern developments concerning weakly nonlinear waves. Throughout, the theory is based on the traditional assumptions that water is inviscid, incompressible with a constant density ρ , and in irrotational flow; that is, it has zero vorticity. It follows that for water waves, the governing equation is Laplace's equation, which is linear, and so all the nonlinearity in the problem resides in the free-surface boundary conditions. There is the kinematic condition that the free surface is a material surface at all times and the dynamic condition that the free surface has constant pressure at all times. The weakly nonlinear theory for water waves is described, which employs some of the basic paradigms for nonlinear waves. The special features that emerge when one considers finite-amplitude water waves are described in the review articles of Schwarz & Fenton (1982) and Dias & Kharif (1999).

Linear Waves

When the governing equations of motion are linearized about the rest state, it is customary to make a Fourier decomposition and seek solutions in which the wave elevation (deviation of the water surface from its rest position) is given by

$$\zeta = a \exp(i(\mathbf{k} \cdot \mathbf{x} - \omega t)) + \text{c.c.}, \quad (1)$$

where $\mathbf{x} = (x, y)$ denotes the horizontal coordinates, and t is the time variable, while $\mathbf{k} = (k, l)$ is the wave number, ω is the wave frequency, and a is the wave amplitude. Here, c.c. denotes the complex conjugate. This elementary disturbance represents a sinusoidal wave propagating in the direction $\mathbf{k}/k$ where $k = |\mathbf{k}| = \sqrt{k^2 + l^2}$, with a phase speed $c = \omega/k$, a wavelength $\lambda = 2\pi/k$, and a period $T = 2\pi/\omega$. The

corresponding fluid velocity is $\mathbf{u} = (u, v)$ and is obtained from a velocity potential (so that $\mathbf{u} = \text{grad } \phi$), where

$$\phi = -ica \frac{\cosh \kappa(z+h)}{\sinh \kappa h} \exp(i(\mathbf{k} \cdot \mathbf{x} - \omega t)) + \text{c.c.} \quad (2)$$

Here, z is the vertical coordinate, and h is the total depth of water in the rest state (that is, the water occupies the region $-h < z < 0$). Note that the horizontal velocity $\mathbf{u}$ is then in phase with the surface elevation, but that the vertical velocity w is $\pi/2$ out of phase, while both velocity components decrease with depth away from the free surface.

Equations (1) and (2) provide a kinematic description of water waves, which to this point means that the conditions of incompressibility and irrotational flow have been satisfied, that the vertical velocity is zero at the bottom, and that the (linearized) kinematic boundary condition that the free surface remains a material surface for all time has been satisfied. To obtain the dynamics, these expressions are substituted into the remaining boundary condition that the free surface is one of constant pressure. This linearized formulation then yields the dispersion relation determining the wave frequency in terms of the wave number,

$$\omega^2 = (gk + \sigma \kappa^3) \tanh(\kappa h), \quad (3)$$

where $\rho\sigma$ is the coefficient of surface tension, which has a value of 74 dyn/cm at 20°C (See **Dispersion relations**). Detailed derivations of (3) and discussions of the consequences for the properties of water waves can be found in many classical and modern texts, see for instance, Lamb (1932), Whitham (1974), Lighthill (1978), or Mei (1983). Indeed, water waves have formed the paradigm for much of our present-day understanding of linear dispersive waves.

There are two branches of the dispersion relation (3), corresponding to waves running to either the right or the left. Note that (3) is isotropic, in that the wave frequency, and hence the phase speed, depend only on the magnitude of the wave number and not its direction. It is apparent from (3) that the effect of surface tension

is significant only when $\kappa > (g/\sigma)^{1/2}$; using the above value for σ this corresponds to $\lambda < 1.73$ cm. Such waves are then usually called capillary waves, while waves with $\kappa < (g/\sigma)^{1/2}$ are called gravity waves. Another useful measure of the effect of surface tension is the Bond number $B = \sigma/g\lambda^2$. When $B < 1/3$, the phase speed $c = \omega/\kappa$ decreases from its long wave value $c_0 = (gh)^{1/2}$, achieved at $\kappa = 0$, to a minimum value of c_m at a wave number $\kappa = \kappa_m$, and then increases without limit as κ increases to infinity. For the case when the Bond number $B > 1/3$, the phase speed increases monotonically from the long wave value c_0 as κ increases from zero. However, the critical depth below which this regime is realized occurs when the Bond number $B = 1/3$, which corresponds to $h = 0.48$ cm. In practice, this is too shallow to ignore the effects of friction and, hence, is usually not regarded as being of any practical interest.

From expressions (2) for the velocity potential and the dispersion relation (3), we see that water waves do not feel the effect of the bottom if $\kappa h \gg 1$. More precisely, if $\kappa h > 2.65$ (or $\lambda/h < 2.37$), then there is less than 1% error in supposing that $h \rightarrow \infty$ and that $\tanh(\kappa h) \rightarrow 1$. This case describes deep water waves, for which the dispersion relation (3) collapses to

$$\omega^2 = g\kappa + \sigma\kappa^3. \quad (4)$$

In this deep water limit, the Bond number $B \rightarrow 0$ ($< 1/3$), so that the dispersion relation for the phase speed $c = \omega/\kappa$ has a minimum value at $\kappa = \kappa_m$ ($= (g/\sigma)^{1/2}$ here) or $c_m = (4g\sigma)^{1/4} = 23.2$ cm/s. There are no sinusoidal waves of the form (1) for any phase speed $c < c_m$, while for any $c > c_m$ there are two classes of deep water waves, gravity waves with $\kappa < \kappa_m$ and capillary waves with $\kappa > \kappa_m$.

Long waves are characterized by the limit $\kappa h \rightarrow 0$, that is, the limit when $\lambda/h \rightarrow \infty$. In this limit, the wave frequency tends to zero, and the wave phase speed tends to $c_0 = (gh)^{1/2}$. In this case, for the reasons discussed above, it is customary to ignore the effects of surface tension, so that there is only one class of waves, namely, gravity waves, which in this limit of $\kappa h \rightarrow 0$ are often referred to as shallow water waves. The fluid velocity is then approximately horizontal and independent of the vertical coordinate z , while at $O(\kappa h)$, the vertical component of the fluid velocity is a linear function of $(z + h)$.

In this linearized system, more general solutions can be built up by Fourier superposition of the elementary solutions (1) over the wave number k in which the dispersion relation (3) is satisfied and the wave amplitude a is allowed to be a function of k . From this process, it can readily be established that a localized initial state will typically evolve into wave packets, with a dominant wave number k and corresponding frequency ω given by (3), within which each wave phase propagates with the phase speed c , but whose envelope

propagates with the group velocity, given by

$$c_g = \nabla_k \omega. \quad (5)$$

The group velocity is the velocity of energy propagation, where the wave energy density is $2\rho(g + \sigma\kappa^2)|a|^2$, being composed of equal parts of potential and kinetic energy. Because water waves are isotropic, the group velocity is in the direction of the wave number k , and has a magnitude

$$c_g = \partial\omega/\partial\kappa = \frac{c}{2} \left\{ \frac{g + 3\sigma\kappa^2}{g + \sigma\kappa^2} + \frac{2\kappa h}{\sinh 2\kappa h} \right\}. \quad (6)$$

Assuming that the Bond number $B < \frac{1}{3}$, it can be shown for gravity waves (defined by the wave number range $0 < \kappa < \kappa_m$) that $c_g < c$, with equality in the long wave limit, $\kappa \rightarrow 0$ when c_g and c tend to c_0 , and at the value $\kappa = \kappa_m$, $c_g = c = c_m$. For capillary waves (defined by the wave number range $\kappa > \kappa_m$), on the other hand, $c_g > c$. In the absence of surface tension (i.e., $B \rightarrow 0$), $c_g < c$ for all wave numbers $\kappa > 0$, and in the deep water limit $c_g \approx c/2$.

Weakly Nonlinear Waves

The theory of linearized waves described in the previous section is valid when initial conditions are such that the waves have sufficiently small amplitudes. However, after a sufficiently long time (or if the initial conditions describe waves of moderate or large amplitudes), the effects of the nonlinear terms in the free surface boundary conditions need to be taken into account. There are three different areas where weak nonlinearity needs to be taken into account, namely, long waves, wave packets, and wave resonances.

Long Waves: Korteweg–de Vries Equation

Initially, we consider unidirectional waves propagating in the positive x -direction, so that the wave number is $k = (k, 0)$. In the long wave limit, $\kappa h \rightarrow 0$, the dispersion relation (3) can be approximated by

$$\omega = c_0 k - \frac{c_0 h^2}{6} \delta k^3 + \dots, \quad \delta = 1 - 3B,$$

where we recall that B is the Bond number measuring the effect of surface tension. To leading order, the waves propagate with the linear long wave phase speed $c_0 = (gh)^{1/2}$. But, after a long time the cumulative effects of weak nonlinearity must be taken into account. When these are balanced against the leading order linear dispersive terms (the $O(k^3 h^3)$ terms above), the result is the well-known Korteweg–de Vries (KdV) equation for the wave elevation

$$\zeta_t + c_0 \zeta_x + \frac{3c_0}{2h} \zeta \zeta_x + \frac{c_0 h^2}{6} \delta \zeta_{xxx} = 0. \quad (7)$$

This equation was derived by Diederik Korteweg and Hendrik de Vries in a now very famous paper published

in 1895 (Korteweg & de Vries, 1895), although in fact Joseph Boussinesq had obtained it earlier in 1877 (Boussinesq, 1877; *See Korteweg–de Vries equation*). Relative to the leading order propagation with the speed c_0 , the time evolution occurs on the nondimensional scale ε^{-3} , where the wave amplitude ζ/h scales with ε^2 and the wave dispersion kh scales with ε (that is, spatial derivatives scale with ε).

Korteweg and de Vries found a family of traveling-wave solutions, periodic waves described by elliptic functions and commonly called cnoidal waves, and the solitary wave solution

$$\zeta = a \operatorname{sech}^2(\gamma(x - Vt)),$$

$$\text{where } V - c_0 = \frac{c_0 a}{2h} = \delta \frac{2c_0 h^2}{3} \gamma^2. \quad (8)$$

The solitary wave has a free parameter, for instance, the amplitude a . When $\delta > 0$ (that is, $B < 1/3$), then the amplitude a is always positive and $V > c_0$. Further, as a increases, the wave speed V and the wave number γ also increase. Although the case when $B > \frac{1}{3}$ has little practical application, it is interesting to note that these conclusions are all reversed as then $\delta < 0$, now, $a < 0$ and $V < c_0$. This solitary wave had earlier been obtained directly from the governing equations independently by Boussinesq (1871) and Rayleigh (1876), who were motivated to explain the now very well-known observations and experiments of John Scott Russell (1844). Curiously, it was not until quite recently that it was recognized that the KdV equation is not strictly valid if surface tension is taken into account and $0 < B < \frac{1}{3}$, as there is then a resonance between the solitary wave and very short capillary waves.

After this ground-breaking work of Korteweg and de Vries, interest in solitary water waves declined until the dramatic discovery of the “soliton” by Zabusky and Kruskal in 1965 (*See Solitons, a brief history*). Through numerical integrations of the KdV equation, they demonstrated that the solitary wave (8) could be generated from quite general initial conditions, and could survive intact collisions with other solitary waves, leading them to coin the term *soliton*. Their remarkable discovery, followed almost immediately by the theoretical work of Gardner, Greene, Kruskal, and Miura (Gardener et al., 1967) showing that the KdV equation was integrable through an inverse scattering transform, led to many other startling discoveries and marked the birth of the soliton theory as we know it today. The implication for water waves is that the solitary wave is the key component needed to describe the behavior of long, weakly nonlinear waves.

An alternative to the KdV equation is the Benjamin–Bona–Mahony (BBM) equation in which the linear dispersive term $c_0 \zeta_{xxx}$ in (7) is replaced by $-\zeta_{xx} V$. It has the same asymptotic validity as the KdV equation and, since it has rather better high wave number properties, is somewhat easier to solve numerically. However, it is

not integrable and, consequently, has not attracted the same interest as the KdV equation.

Both the KdV and BBM equations are unidirectional. A two-dimensional version of the KdV equation is the KP equation (Kadomtsev & Petviashvili, 1970; *See also Kadomtsev–Petviashvili equation*),

$$\left(\zeta_t + c_0 \zeta_x + \frac{3c_0}{2h} \zeta \zeta_x + \frac{c_0 h^2}{6} \delta \zeta_{xxx} \right)_x + \frac{c_0}{2} \zeta_{yy} = 0. \quad (9)$$

This equation includes the effects of weak diffraction in the y -direction, in that y -derivatives scale as ε^2 whereas x -derivatives scale as ε . When $\delta > 0$ ($0 \leq B < \frac{1}{3}$), this is the KP-II equation, and it can be shown that then the solitary wave is stable to transverse disturbances. On the other hand, if $\delta < 0$ ($B > \frac{1}{3}$), this is the KP-I equation for which the solitary wave (8) is unstable; instead this equation supports “lump” solitons. Both KPI and KP-II are integrable equations. To take account of stronger transverse effects and/or to allow for bi-directional propagation in the x -direction, it is customary to replace the KdV equation with a Boussinesq system of equations. These combine the long wave approximation to the dispersion relation with the leading order nonlinear terms and occur in several asymptotically equivalent forms.

Wave Packets: Nonlinear Schrödinger Equation

The linear theory of water waves predicts that a localized initial state will typically evolve into wave packets, with a dominant wave number k and corresponding frequency ω given by (3), within which each wave phase propagates with the phase speed c , but whose envelope propagates with the group velocity c_g (5, 6). After a long time, the packet tends to disperse around the dominant wave number, which tendency may be opposed by cumulative nonlinear effects. In the absence of surface tension, the outcome for unidirectional waves is described by the nonlinear Schrödinger (NLS) equation, for the wave amplitude $A(x, t)$; that is, the wave elevation is $\zeta = A \exp i(kx - \omega t) + \text{c.c.}$ to leading order,

$$i(A_t + c_g A_x) + \frac{1}{2} \lambda A_{xx} + \mu |A|^2 A = 0, \quad (10)$$

and the coefficients are given by

$$\lambda = \frac{\partial^2 \omega}{\partial k^2},$$

$$\mu = -\frac{\omega k^2}{16S^4} (8C^2 S^2 + 9 - 2T^2) + \frac{\omega}{8C^2 S^2} \frac{(2\omega C^2 + k c_g)^2}{gh - c_g^2},$$

where

$$C = \cosh(kh), \quad S = \sinh(kh), \quad T = \tanh(kh).$$

For water waves, the NLS equation was first derived by Zakharov (1968) for the case of deep water, and

then by Hasimoto and Ono (1972) for finite depth. An analogous equation can be derived for nonzero surface tension in which the nonlinear coefficient μ will take a different value, but for reasons discussed below, it is not so useful in that case. In deep water ($kh \rightarrow \infty$) the coefficient $\mu \rightarrow -\omega k^2/2 < 0$. In general, $\mu < 0 (> 0)$ according as $kh > (<) 1.36$.

Like the KdV equation, the NLS equation is integrable with an associated inverse scattering transform, a result first shown by Zakharov and Shabat (1972). There are two cases, the so-called focusing NLS equation when $\lambda\mu > 0$ and the defocusing NLS equation when $\lambda\mu < 0$. For water waves, $\lambda = \partial c_g / \partial k < 0$, and so we have the focusing (defocusing) NLS equation according as $kh > (<) 1.36$. The focusing NLS equation has solitary wave solutions (bright solitons), given by

$$A = a \operatorname{sech}(\gamma(x - c_g t)) \exp(-i\Omega t), \quad (11)$$

where $\mu a^2 = \lambda \gamma^2$, $\Omega = -\frac{1}{2} \mu a^2$.

On the other hand, the defocusing NLS equation has no such solitary wave solutions which decay to zero at infinity. Instead, it has solitary waves riding on a nonzero background (dark solitons). A key property of the NLS equations is that plane waves are modulationally unstable (stable) in the focusing (defocusing) case. That is, the NLS equation has the exact plane wave solution,

$$A = A_0 \exp(i\mu |A|^2 t), \quad (12)$$

which is then perturbed with a small-amplitude modulation proportional to $\exp(iKx - \sigma t)$. It is readily found that the growth rate σ is given by

$$\sigma = K^2 \left(\lambda \mu A_0^2 - \frac{\lambda^2 K^2}{4} \right). \quad (13)$$

Thus, in the focusing NLS case when $\lambda\mu > 0$, there is a positive growth rate for modulation wave numbers K such that $K < 2(\lambda/\mu)^{1/2}|A_0|$. On the other hand, σ is purely imaginary for all K in the defocusing case when $\lambda\mu < 0$. The implication for water waves is that plane Stokes waves in deep water ($kh > 1.36$) are unstable. This remarkable result was first discovered by Benjamin and Feir in 1967, by a different theoretical approach, and has since been confirmed in experiments. The maximum growth rate occurs for $K = K_m = (\lambda/\mu)^{1/2}|A_0|$, and the instability is due to the generation of side bands with wave numbers $k \pm K_m$. As the instability grows, the full NLS equation (10) is needed to describe the long-time outcome of the collapse of the uniform plane wave into several soliton wave packets, each described by (11).

When the effects of modulation in the transverse y -direction are taken into account, so that the wave amplitude is now given by $A(x, y, t)$, the NLS equation is replaced by the Benney–Roskes system (Benney

& Roskes, 1969), also widely known as the Davey–Stewartson equations (Davey & Stewartson, 1974),

$$i(A_t + c_g A_x) + \frac{1}{2} \lambda A_{xx} + \frac{1}{2} \delta A_{yy} + \mu |A|^2 A + U A = 0, \quad (14)$$

$$\alpha U_{xx} + U_{yy} + \beta (|A|^2)_{yy} = 0, \quad (15)$$

where the coefficients μ and λ are those defined in (10), while

$$\delta = \frac{c_g}{k}, \quad \alpha = 1 - \frac{c_g^2}{gh},$$

$$gh\beta = \frac{\omega}{8C^2 S^2} (2\omega C^2 + k c_g)^2.$$

Here, the surface tension has been set to zero. If surface tension effects are included, a similar equation holds but with different values for the coefficients (Djordjevic & Redekopp, 1977). Note that $\lambda\delta < 0$ and $\alpha > 0$, so that the equation for A is hyperbolic, but that for U it is parabolic. The variable U which appears here is a wave-induced mean flow, which tends to zero in the limit of deep-water waves, $kh \rightarrow \infty$. This system (14) again has the plane wave solution (12), whose stability can be analyzed in a manner similar to that described above in the context of the NLS equation. The outcome is that now instability can occur for all values of kh and occurs in a band in the $k-l$ plane where k and l are the modulation wave numbers. The instability is purely two-dimensional when $kh < 1.36$, and the band becomes narrower and the growth rate weaker as $kh \rightarrow 0$. For more details, see Benney and Roskes (1969) or Mei (1983).

Wave Resonant Interactions

A superposition of weakly nonlinear waves, each of which is given by (1) with a wave number k_n , $n = 1, 2, \dots, N$, and a corresponding frequency $\omega_n(k_n)$, $n = 1, 2, \dots, N$, each satisfying the dispersion relation (3), interact resonantly whenever

$$k_1 + k_2 + \dots + k_N = 0,$$

and

$$\omega_1 + \omega_2 + \dots + \omega_N = \Omega.$$

Here, Ω is a detuning term, so that exact resonance is achieved whenever $\Omega = 0$. The most prominent interactions are triad interactions; that is, $N = 3$, followed by the quartet interactions when $N = 4$, and so on. In a resonant interaction, energy is exchanged between the Fourier components in a periodic manner, assuming that dissipation is absent. For instance, the set of equations describing a triad interaction is (Craig, 1985)

$$A_{1t} + c_{g1} \cdot \nabla A_1 = \frac{\partial D}{\partial \omega_1} \mu A_2^* A_3^* \exp(-i\Omega t), \dots,$$

where $A_n(x, t)$ is the amplitude of the n th mode, $D(\omega, \mathbf{k}) = 0$ is the dispersion relation, μ is a coefficient, and the superscript “*” denotes the complex conjugate. Remarkably, these equations are integrable for exact resonance ($\Omega = 0$) (Zakharov & Manakov, 1973).

For water waves in the absence of surface tension, the dispersion relation does not allow for triad interactions. Hence, the dominant resonance is a quartet interaction, as first shown by Phillips (1960). The four wave numbers making up the quartet are two-dimensional (i.e., the y -wave number components are generally not zero), and the allowed wave number vectors can be determined graphically from Phillips’ “figure-of-eight” diagram. The interaction equations for a discrete quartet of waves is analogous to that displayed above for a triad interaction. Further, in deep water ($kh \rightarrow \infty$), Craig & Worfolk (1995) have shown that in the Birkhoff normal form for these interaction equations, the coefficients vanish for all nongeneric resonant terms and the remaining system is then integrable. However, the same is not the case for quintet interactions.

When considering a continuous spectrum of gravity waves, the resulting evolution of a spectral component is described by Zakharov’s integral equation, first derived in the deep water limit by Zakharov (1968). Krasitskii (1994) later employed canonical transformations to obtain a more desirable Hamiltonian form (see also the review by Dias & Kharif, 1999). In this equation, usually truncated at the third order in wave amplitude, the evolution of the spectral component $A(\mathbf{k}, t)$, which is the spatial Fourier transform of $\eta(\mathbf{x}, t)$, is determined essentially by quartet interactions, since the nonresonant triad interactions are removed by a canonical transformation. This integral evolution equation contains much of the previous weakly nonlinear theory, in that the discrete interaction equations and the NLS equation can be derived from it. It also forms the basis for a statistical description of water waves and can then be used to describe the ocean wave spectrum.

When surface tension is taken into account, then triad interactions are possible (i.e., $N = 3$ in (??)). The most well-known example occurs when $\mathbf{k}_1 = \mathbf{k}_2 = -\mathbf{k}_3/2$, and is a second harmonic resonance in that then $\omega_1 = \omega_2 = -\omega_3/2$. It was first noted by Wilton (1915) and leads to a phenomenon known as Wilton’s ripples. In general, the existence of triad resonances implies that capillary-gravity waves undergo wave-wave interactions on a faster time scale than pure gravity waves.

WAVE OF TRANSLATION

Translational invariance is one of the fundamental symmetries of continuum nonlinear partial differential equations (PDEs). Such a symmetry is present when the equation of interest remains unchanged under the transformation $x \rightarrow x + \varepsilon$. Typically, partial differential equations that contain only derivatives with respect to the spatial variable x (but no explicit dependence on x) possess this symmetry.

The topic of symmetries and their role in bifurcation theory is a very large subject, a detailed discussion of which can be found, for example in Golubitsky & Schaeffer (1995) and Golubitsky (1988). Here, our scope is much narrower in giving a perspective of translational symmetry and its role in the existence, bifurcation, or absence of traveling wave solutions in some Hamiltonian and dissipative classes of PDEs.

To make our discussion of this subject more definitive, we will introduce a rather general class of dissipative or Hamiltonian PDEs of the form

$$\{u_t, u_{tt}\} = u_{xx} + f(u). \quad (1)$$

The paradigm of Equation (1) is dissipative (that is, of the reaction-diffusion type), if a one-time derivative of the field u is used in the left-hand side. On the other hand, the model is Hamiltonian if the second time derivative is used on the left-hand side. While the model is written as a single component model in a one-dimensional setting, it can be easily generalized in multiple components/dimensions. In the former case, u becomes a vector, while in the latter, the spatial second partial derivative is substituted by the Laplacian operator. We should note in passing that while here we consider the Hamiltonian and dissipative cases, there are many models which lie between the conservative and diffusion limits. Numerous examples of this type can be found in Kivshar & Malomed (1989).

It can be immediately observed that the translational symmetry mentioned above is present in the model of Equation (1). A straightforward example of its absence would be the case of a “reaction term” $f(u, x)$, i.e., one explicitly dependent on x . Let us now explore the implications of this symmetry for the static problem of Equation (1) and then for the corresponding dynamic problem.

For the static problem (i.e., for solutions $u = g(x)$ that satisfy $u_{xx} + f(u) = 0$), the presence of the invariant direction signifies that the solution can be translated along the group orbit of this invariance.

Otherwise stated, there is a one parameter infinity of solutions (alternatively, a degeneracy of solutions) due to the available freedom to select solutions along the symmetry direction. In practical terms, this means that if $u = g(x)$ is a solution, then $u = g(x - x_0)$ is also a solution and arbitrary translations of the solution satisfy the original equation. Furthermore, this feature bears consequences on the linear stability around the solution. In particular, looking for the linear stability of the solution $u = g(x)$, we use the linearization $u = g(x) + \varepsilon \exp(\lambda t) w(x)$, which to $O(\varepsilon)$, yields the eigenvalue problem:

$$\{\lambda, \lambda^2\} w = w_{xx} + f'(g(x))w. \quad (2)$$

Given that $g(x)$ satisfies the $u_{xx} + f(u) = 0$, differentiation of the latter immediately yields that (due to the absence of the explicit spatial dependence and hence due to the symmetry) $w = u_x \equiv g'(x)$ satisfies Equation (2), with $\lambda = 0$ (for the dissipative system) or $\lambda^2 = 0$ (for the Hamiltonian system). Hence, the existence of the symmetry generates a single (for the dissipative) or a pair (for the Hamiltonian) of eigenvalues at the origin of the spectral plane (i.e., with $\lambda = 0$). This is the neutral eigendirection connected with the symmetry that is often referred to as a Goldstone mode.

Furthermore, in the Hamiltonian version of the system, the presence of such eigenmodes, and of their corresponding symmetries, is intimately connected with conservation laws (through Noether's theorem; see for example the discussion in Arnol'd (1989); Sulem & Sulem (1999)). The invariance with respect to translations is directly related with the conservation of linear momentum, which in the case of Equation (1) is of the form

$$P = \int_{-\infty}^{\infty} u_t u_x \, dx. \quad (3)$$

We now turn to the dynamic consequences of the symmetry. The translational symmetry is directly related to the traveling of solutions. In the case of Hamiltonian (especially continuum) systems, there may be extra symmetries that may allow the construction of traveling solutions from stationary ones. In the case of Equation (1), such a symmetry is the Lorentz invariance $[x \rightarrow x' = \gamma(x - vt), t \rightarrow t' = \gamma(t - vx/c^2), \gamma = 1/\sqrt{1 - v^2/c^2}]$, which allows one to boost the solutions to any “subsonic” speed. In other cases, such as the one of the nonlinear Schrödinger equation, the corresponding symmetry, is the Galilean invariance. Hence, in Hamiltonian systems, due to the additional symmetry, traveling and standing solutions are often, in some sense, equivalent. On the other hand, for dissipative systems, such equivalence is typically absent. In the latter case, we look for traveling wave solutions in the form $u = u(\xi)$, where $\xi = x - ct$ is the traveling wave variable. This transformation leads to the so-called traveling wave frame (TWF) equation of

motion (i.e., we travel together with the solution and, hence, observe it as a steady one) of the form

$$u_t = u_{\xi\xi} + cu_{\xi} + f(u). \quad (4)$$

By solving the steady-state problem of Equation (4) (notice: an ordinary differential equation (ODE) problem to find special solutions of the PDE), we can identify the traveling-wave solutions of Equation (1). In dissipative systems, the absence of additional symmetries typically allows for isolated solutions of the TWF ODE rather than monoparametric families of such solutions. Notice that here we have in mind fixed model parameter values (but not fixed initial condition parameters, such as, for example, energy). Furthermore, we do not discuss the mechanisms (in dissipative systems) of selection of a given speed (which is related to issues of stability). Such examples and a detailed discussion can be found in Xin (2000). A typical example is the bistable nonlinearity where $f(u) = 2u(u-1)(\mu-u)$, for which a front solution of the form

$$u(x, t) = \frac{1}{2} \left[1 - \tanh \left(\frac{x - x_c(t)}{2} \right) \right], \quad (5)$$

exists, where $x_c = x_c^{\text{in}} + ct$ and x_c^{in} is the original position of the center, while the speed c is connected to the parameter μ through

$$c = 1 - 2\mu. \quad (6)$$

In view of the above comments, in energy conserving systems, typically standing and traveling solutions co-exist, while in dissipative systems one can (locally) have solutions either of the former or of the latter type. In fact, as parameters are varied in dissipative settings, traveling solutions may bifurcate from standing ones, through the so-called drift pitchfork bifurcation (Kness et al., 1992; see also Malomed & Tribelsky (1984) and Couillet & Iooss, 1990). It is worth noting that recently, a template-based technique has been proposed that dynamically factors out translational invariance (and other continuous symmetries) (Rowley & Marsden, 2000; Rowley et al., 2003).

Discrete Systems and Symmetry Breaking

An interesting variation of the above presented scenario occurs in (spatially) discrete systems. In this case, generic discretizations of the original problem of Equation (1) no longer preserve the symmetry with respect to continuum translations. Instead, only an integer shift invariance persists in this discrete limit of the equation:

$$\{\dot{u}_n, \ddot{u}_n\} = \Delta_2 u_n + f(u_n), \quad (7)$$

where $\Delta_2 u_n = (u_{n+1} + u_{n-1} - 2u_n)/h^2$ is the discrete Laplacian for a lattice of spacing h . In this case, from

the informative Taylor expansion of the form

$$\Delta_2 u_n = \sum \frac{2h^{2j-2}}{(2j)!} \frac{d^{2j}u}{dx^{2j}}, \quad (8)$$

we deduce the following conclusions:

- discreteness is a singular higher-order derivative perturbation to the continuum limit;
- to all orders in this asymptotic expansion, the right-hand side is translationally invariant. Hence, the breaking of the translational symmetry can only occur beyond all algebraic orders and thus has to be an exponentially small effect.

A manifestation of this exponentially small symmetry breaking effect is given by the fact that there are now two (lattice shift invariant) stationary wave states in the lattice context. One of these solutions is centered on a lattice site and one is centered between two consecutive lattice sites (instead of a single translationally invariant steady state in the continuum limit). One of these solutions is stable and one is unstable. The energy difference between the two (which mirrors the amount of symmetry breaking and hence should be exponentially small, that is, $\Delta E \sim \exp(-\pi^2/h)$) is the celebrated Peierls–Nabarro barrier. For a detailed discussion of these issues, see, for example, the review by Kevrekidis et al. (2001).

From the above, we can infer that the generic effect of discreteness in breaking translational invariance is to generate an exponentially small (in the natural lattice spacing parameter) shift periodic (in fact approximately trigonometric) potential. The center of mass of the waves propagates inside the Peierls–Nabarro barrier. There is considerable interest in shearing this potential with an external (constant) field.

A constant external force F introduces a term in the potential energy $\sim Fu$, generating a washboard potential for the motion of the wave. If the external field becomes sufficiently strong, then one can infer that a saddle-node (in fact, infinite period; the so-called SNIPER) bifurcation will occur in which the stationary states (the maxima and minima of the potential, that is, the saddles and nodes) will disappear and traveling waves will arise. Scaling analysis predicts and numerical results verify (Kaldko et al., 2000; Kevrekidis et al., 2001; Carpio & Bonilla, 2001) that the relevant bifurcation will yield waves of speed

$$c \sim (F - F_c)^{1/2}, \quad (9)$$

where F is the constant external field and F_c is its critical value. The energy landscapes for the cases of $F=0$, $F < F_c$, and $F > F_c$ are shown in Figure 1. This scenario happens in the dissipative case, but one can also analyze the Hamiltonian case in the same manner.

Finally, it should be noted that while the above scenario will be the generically relevant one, there

Figure 1. The (potential) energy (P) landscape for generic DDE models in the case of $F = 0$ (top panel), $F < F_c$ (middle panel) and $F > F_c$ (bottom panel), as a function of the position of the kink center.

are exceptions to the rule of absence of a continuum-like symmetry in the lattice setting. Let us consider, for example, the discretization of the Hamiltonian PDE:

$$\ddot{u}_n = \Delta_2 u_n + \frac{F(u_{n+1}) - F(u_{n-1})}{u_{n+1} - u_{n-1}}. \quad (10)$$

It can be seen that the equation of motion has a conservation law of the form

$$P = \sum \dot{u}_n(u_{n+1} - u_{n-1}) \quad (11)$$

which is the discrete analog of Equation (3). In this case, the discrete equation preserves a “ghost” of the continuum symmetry and maintains the multiplicity of Goldstone modes of the continuum problem (Kevrekidis, 2003).

In conclusion, translational invariance is a symmetry that plays a significant role in the context of both partial-differential as well as differential-difference (i.e., lattice) equations. In the former, it is typically present (unless an explicit spatial dependence occurs)

and has both static as well as kinematic consequences on the solutions of the problem and their stability. In the discrete setting, the symmetry is generically absent and its absence plays a critical role in diversifying kinematic and dynamic phenomena on the lattice (see, for example, Kevrekidis, et al. (2001)) from their continuum siblings. However, it is possible to construct discretizations that respect a discrete conservation law reminiscent of the one imposed by the continuum symmetry group. In the nongeneric case, the lattice dynamics can be significantly closer to their continuum counterparts.

WAVE PACKETS, LINEAR AND NONLINEAR

Because linear wave systems have elementary solutions of the form $e^{i(kx-\omega t)}$, it is often convenient to write the general solution of an initial value problem as an integral of Fourier components. Thus,

$$u(x, t) = \frac{1}{2\pi} \int_{-\infty}^{\infty} F(k) e^{i(kx-\omega t)} dk, \quad (1)$$

where $F(k)$ is the Fourier transform of $u(x, 0)$. Initial conditions thus determine the Fourier transform, each component of which evolves independently with frequency ω related to wave number k through the dispersion relation

$$\omega = \omega(k). \quad (2)$$

Unless $\omega = k$, different components in Equation (1) travel at different speeds (ω/k), and an initially localized wave spreads out or “disperses,” hence the name.

A wave packet is a special form of Equation (1) with the largest Fourier components lying close to some wave number (k_0) and the corresponding frequency (ω_0). In other words, the initial conditions $u(x, 0)$ are selected so that $F(k)$ has its maximum value at $k = k_0$, falling rapidly with increasing $|k - k_0|$. This suggests writing the dispersion relation as a power series about k_0 . With the notation

$$\omega = \omega_0 + b_1(k - k_0) + b_2(k - k_0)^2 \quad (3)$$

(which assumes that the system has no higher than second derivatives with respect to x), Equation (1) becomes

$$u(x, t) = e^{i(k_0 x - \omega_0 t)} \frac{1}{2\pi} \int_{-\infty}^{\infty} F(k) e^{i[(k-k_0)x - b_1(k-k_0)t - b_2(k-k_0)^2 t]} dk, \quad (4)$$

where the factor $e^{i(k_0 x - \omega_0 t)}$ is a carrier wave with a velocity $v_c = \omega_0/k_0$, shown in Figure 1(a). Riding over (or multiplying) the carrier is an envelope wave

$$\phi(x, t) = \frac{1}{2\pi} \int_{-\infty}^{\infty} F(\kappa + k_0) e^{i(\kappa x - b_1 \kappa t - b_2 \kappa^2 t)} d\kappa, \quad (5)$$

where the variable of integration has been changed from k to $\kappa \equiv k - k_0$.

Figure 1. (a) The real part of a linear wave packet, showing the envelope (dashed lines) and the carrier (full line), as in Equation (4). (b) The real part of a soliton solution of Equation (7).

Taking the time derivative of Equation (5), one finds

$$\begin{aligned} \frac{\partial \phi}{\partial t} &= \frac{1}{2\pi} \int_{-\infty}^{\infty} -i(b_1 \kappa + b_2 \kappa^2) F(\kappa + k_0) \\ &\quad \times e^{i(\kappa x - b_1 \kappa t - b_2 \kappa^2 t)} d\kappa \\ &= -b_1 \frac{\partial \phi}{\partial x} + i b_2 \frac{\partial^2 \phi}{\partial x^2}, \end{aligned}$$

which can be written as

$$i \left(\frac{\partial \phi}{\partial t} + b_1 \frac{\partial \phi}{\partial x} \right) + b_2 \frac{\partial^2 \phi}{\partial x^2} = 0. \quad (6)$$

Equation (6) is a partial differential equation that governs time evolution of the envelope for a linear wave packet solution of a second-order equation. Assuming b_2 is not too large (weak dispersion), the envelope moves with the velocity $v_c \doteq b_1 = d\omega/dk|_{k=k_0}$, as in Figure 1(a).

Up to this point, the discussion has remained within the realm of linear theory, but now assume that nonlinear effects alter Equation (6) to

$$i \left(\frac{\partial \phi}{\partial t} + b_1 \frac{\partial \phi}{\partial x} \right) + b_2 \frac{\partial^2 \phi}{\partial x^2} + \alpha |\phi|^2 \phi = 0, \quad (7)$$

with the nonlinear (amplitude-dependent) dispersion relation $\omega = b_1 \kappa + b_2 \kappa^2 - \alpha |\phi|^2$. Equation (7) is the nonlinear Schrödinger (NLS) equation, for which the following comments are relevant:

- If ϕ is assumed independent of x , Equation (7) has the plane wave solution

$$\phi = \phi_0 e^{i\alpha |\phi_0|^2 t}, \quad (8)$$

which may or may not be stable.

- With $\alpha b_2 < 0$, this plane wave is stable (Whitham, 1974). If $\alpha b_2 > 0$, on the other hand, the plane wave experiences Benjamin–Feir instability, out of which emerge stable NLS solitons (Benjamin & Feir, 1967; Ostrovsky, 1967).

- The term $b_2(\partial^2\phi/\partial x^2)$ introduces wave dispersion into the problem at the lowest order of approximation. Similarly, the term $\alpha|\phi|^2\phi$ introduces nonlinearity at the lowest order of approximation. Thus, the NLS equation is generic, arising whenever one wishes to consider lowest order effects of dispersion and nonlinearity on a wave packet, including nonlinear optics (Kelley, 1965), deep water waves (Benney & Newell, 1967), and acoustics (Ostrovsky & Potapov, 1999).
- Unstable NLS wave packets decay into one or more solitons. Choosing $b_1 = 0$, $b_2 = 1$, and $\alpha = 2$ in Equation (7), for example, a family of NLS solitons is (Zakharov & Shabat, 1972)

$$u(x, t) = a \exp \left[i \frac{v_c}{2} x + i \left(a^2 - \frac{v_c^2}{4} \right) t \right] \times \text{sech} [a(x - v_c t - x_0)], \quad (9)$$

one of which is sketched in Figure 1(b).

Beyond the superficial similarities between Figures 1(a) and (b), the differences are profound. In the linear wave packet of Figure 1(a), the shape of the envelope is determined by initial conditions and their subsequent time evolution, as in Equation (6). In the NLS soliton of Figure 1(b), on the other hand, the envelope shape is determined through a dynamic balance between the influences of dispersion and nonlinearity, as expressed by the last two terms of Equation (7).

WAVE PROPAGATION IN DISORDERED MEDIA

Although nonlinear partial differential equations with constant coefficients well describe main features of

numerous nonlinear systems, understanding of many natural phenomena or experimental data requires taking into account the imperfectness of media which often have random character of two main types: time-dependent fluctuations and random spatial inhomogeneities (both may appear simultaneously). A thermal bath and quantum laser fluctuations are examples of the first type while impurities in crystal lattices, irregular variations of dielectric permittivity, and imperfectness of optical fibers are of the second type. Modeling of such phenomena requires nonlinear evolution equations with stochastic terms.

If a physical process is described by a field $u(t, \mathbf{r})$ that in an idealized situation is governed by a nonlinear equation $N[u] = 0$, then including irregularities (fluctuations) of the medium in the consideration will result in an equation of the type $N[u] = \varepsilon(t, \mathbf{r})R[u]$, where $\varepsilon(t, \mathbf{r})$ is a random field and a (possibly nonlinear) operator $R[u]$ depends on physical nature of randomness. Such problems are difficult and still not well understood. The main difficulty arises because nonlinearity invalidates powerful methods of the linear theory (such as the Fourier transform) which allow one to relate stationary and nonstationary problems or introduce a Gaussian approach, allowing decoupling of high-order moments.

From the physical point of view, we can distinguish several important factors that must be taken into account, including generation of high harmonics resulting in nontrivial changes of the field statistics, creation of rather stable localized excitations (which have no analogy in the linear theory), and the multistability phenomenon.

Let us illustrate these issues with two examples: the nonlinear Schrödinger equation for a complex field $u(t, x)$:

$$i \frac{\partial u}{\partial t} + \frac{\partial^2 u}{\partial x^2} + 2|u|^2 u = \varepsilon(t, x)R[u] \quad (1)$$

and the nonlinear Klein–Gordon equation for a real scalar field $u(t, x)$

$$\frac{\partial^2 u}{\partial t^2} - \frac{\partial^2 u}{\partial x^2} + u - u^3 = \varepsilon(t, x)R[u]. \quad (2)$$

These models represent some essential differences. First, at $\varepsilon = 0$ Equations (1) and (2) are, respectively, integrable and nonintegrable. Second, the former model allows a solution in a form of a monochromatic wave and hence admits formulation of a stationary problem while harmonic generation is an indispensable property of the second model. Finally, their solitary wave solutions at $\varepsilon(t, x) = 0$ are of different types: a dynamical soliton (in the restricted mathematical sense) in case (1) and a topological kink in case (2).

The random field $u(t, x)$, being a functional of $\varepsilon(t, x)$, is completely determined by a set of all $(n + m)$ -

order moments

$$\langle u(t_1, x_1) \cdots u(t_n, x_n) \bar{u}(t_{n+1}, x_{n+1}) \cdots \bar{u}(t_{n+m}, x_{n+m}) \rangle, \quad (3)$$

where averaging is designated by the angular brackets and is provided over all realizations of $\varepsilon(t, x)$, when they are known. Because a Gaussian approximation is not applicable in nonlinear theory, the generic situation is that an $(n + m)$ -order momentum cannot be expressed only through lower-order correlation functions. Moreover, temporal evolution of the mean field may drastically differ from the evolution of the field itself.

This is illustrated by Equation (1) with $\varepsilon(t, x) R[u] \equiv -f(t)xu(t, x)$, $f(t)$ being a Gaussian random process with

$$\langle f(t) \rangle = 0 \quad \text{and} \quad \langle f(t)f(t') \rangle = \sigma^2 \delta(t - t'), \quad (4)$$

where σ is the dispersion of the fluctuations (Besieris, 1980). This equation is exactly solvable with the one-soliton solution

$$u(t, x) = \eta \frac{\exp \{ i [\mu(t)x + \eta^2 t - \beta(t)] \}}{\cosh \{ \eta [x - 2\xi(t)] \}}, \quad (5)$$

where $\dot{\mu}(t) = f(t)$, $\mu(t) = \dot{\xi}(t)$, and $\dot{\beta} = \mu^2$ (a dot indicates a time derivative). Being interested in the evolution of the soliton intensity, which depends on $\xi(t)$ only, one can calculate the distribution

$$\begin{aligned} P(\xi, t) &= \int_{-\infty}^{\infty} \langle \delta(v - \dot{\xi}(t)) \delta(\xi - \xi(t)) \rangle dv \\ &= \sqrt{\frac{3}{2\sigma^2 t^3}} \exp \left(-\frac{3\xi^2}{2\sigma^2 t^3} \right). \end{aligned} \quad (6)$$

Although the solution undergoes Brownian motion without any distortion, it follows from Equations (5) and (6) that its mean intensity is described by the Gaussian asymptotics

$$\langle u(t, x) \bar{u}(t, x) \rangle \approx \eta \sqrt{\frac{3}{2Dt^3}} \exp \left(-\frac{3x^2}{8\sigma^2 t^3} \right)$$

at $t \gg \frac{1}{(\sigma\eta)^{2/3}}$.

In a general situation when exact solutions are not available, the problem becomes dependent on its statement and on the physical characteristics to be determined. The main statements of the problem are listed below.

Stationary Wave Scattering

This is a generalization of the problem of a wave transmission through a random slab to the nonlinear case. In the linear theory, the wave intensity decays exponentially with the slab width

(Anderson localization). In the nonlinear case, one considers a monochromatic solution of Equation (1): $u(t, x) = (k/\sqrt{2}) \exp(-ik^2 t) \phi(x)$, where $\varepsilon(t, x) \equiv k^2 \varepsilon_0(x)$, $\varepsilon_0(x)$ being a random function in the interval $0 < x < L$ and zero outside this interval, and $R[u] \equiv u(t, x)$. Then $\phi(x)$ satisfies the equation

$$\frac{d^2 \phi}{dx^2} + k^2(1 + \varepsilon_0(x) + |\phi|^2) \phi = 0. \quad (7)$$

In order to describe an incidence of a plane wave on the random layer from the right, one imposes

$$\phi(x) = \begin{cases} a [e^{ik(L-x)} + R(L, w)e^{ik(x-L)}], & x \geq L, \\ T(L, w)e^{-ikx}, & x \leq 0 \end{cases} \quad (8)$$

and the conditions of the continuity of the field $\phi(x)$ and of its derivative $d\phi(x)/dx$ at the boundaries of the layer, $x = 0$ and $x = L$ (see Figure 1).

The coefficients a , $R(L, w)$ and $T(L, w)$ are amplitudes of the incident wave, reflection and transmission coefficients. The last two quantities depend on the slab width L and on the intensity of the incident wave $w = a^2$. Using the imbedding method (Klyatskin, 1988), one can obtain a nonlinear partial differential equation for the reflection coefficient as a function of L and w , which (upon applying the method of characteristics) results in a system (Doucot & Rammal, 1987)

$$\frac{dR_1}{dL} = -2kR_2 - kR_2(1 + R_1)(\varepsilon(L) + w|1 + R|^2), \quad (9)$$

$$\begin{aligned} \frac{dR_2}{dL} &= 2kR_1 + \frac{k}{2} [(1 + R_1)^2 - R_2^2] \\ &\quad \times (\varepsilon(L) + w|1 + R|^2), \end{aligned} \quad (10)$$

where $R_1(L) = \Re(R(L, w))$, $R_2(L) = \Im(R(L, w))$,

$$w(L) = \frac{w(0)}{1 - |R(L, w)|^2}, \quad (11)$$

and the initial conditions are $R_1(0) = R_2(0) = 0$. Formula (11) allows us to understand two essentially different statements of the scattering problem. Indeed, (9) and (10) are dynamical equations for the characteristics that pass either through the point $(L = 0, w(0) = w_0)$, if the output intensity of the wave w_0 , is given, or through the point $(L, w(L))$ if the input intensity is given (called fixed input and fixed output problems). In the former case, while increasing L , one follows the characteristic starting with its initial position. To solve a fixed output problem, one must determine a characteristic or characteristics which cross the point $(L, w(L))$ (having different starting points). As there may be more than one characteristic, multistability occurs (for another way of understanding the multistability phenomenon, see Knapp et al. (1991)).

Consider the fixed output problem (w_0 is given) in the case of weak Gaussian fluctuations, when

Figure 1. To the statement of the stationary scattering problem.

$\langle \varepsilon_0(x) \rangle = 0$, $\langle \varepsilon_0(x)\varepsilon_0(x') \rangle = D\delta(x - x')$, and $L_{\text{loc}} \gg \lambda$, L_{nl} where $L_{\text{loc}} = 1/(Dk^2)$ is the Anderson localization length of the underlying linear system, $\lambda = 2\pi/k$ is the incident wavelength, and $L_{\text{nl}} = 1/(w_0k)$ is the effective nonlinear length characterizing change of the reflection coefficient due to the nonlinearity. Starting with the region of a relatively strong nonlinearity, $L_{\text{nl}} \ll \lambda$, one can define a period of motion $L_p = \int_0^{2\pi} (d\theta/dL)^{-1} d\theta \approx L_{\text{nl}}$ (here $\theta = \arg R$) and study weak drift of trajectories of “dynamical system” (9), (10) due to the random perturbations over one period L_p (providing averaging over θ). The main result can be formulated as $\langle 1/T^2 \rangle = O(L^2)$ and decay of the fluctuations of $\langle \ln T^2 \rangle$ at $L \rightarrow \infty$ (Doucot & Rammal, 1987). Similar results, obtained for a step-like random function $\varepsilon_0(x)$ (Fröhlich et al., 1986). Thus, compared with the linear theory, the nonlinearity does not change the property of $\ln T^2$ to be a self-averaging value, but results in change of the decay law for the decay of the transmission coefficient from the exponential one to a power one. However, when the intensity of the wave becomes small enough and the effect of back-scattering becomes dominating, one can recover the exponential decay law $T \sim \exp(-L/L_{\text{loc}})$. The transition between two regions with the different laws of the decay of the reflection coefficient happens at $L_0 \sim L_{\text{loc}} \ln(1/w_0)$: the law is power at $L > L_0$ and is exponential at $L < L_0$.

Interaction of a Wave Packet with a Random Layer

As this case cannot be reduced to the study of a stationary problem, the statement of the problem and physical characteristics describing wave scattering must be redefined (compared with the previous case of stationary scattering). Consider the Cauchy problem with a given initial field distribution that decays sufficiently rapidly at infinity. The main task can be formulated as a description of the evolution of the wave-packet characteristics during its propagation. Such a statement acquires a special

meaning in systems that possess stable solitary wave solutions in the unperturbed ($\varepsilon = 0$) limit and in which the randomness is weak enough. For relatively large temporal intervals, the nonlinear field can be represented in the form $u(t, x) \approx u_{\text{ad}}(t, x) + u_{\text{rad}}(t, x)$, where $u_{\text{ab}}(t, x)$ is a function having the same form as the unperturbed solitary wave but now with slowly varying parameters (adiabatic approximation) and $u_{\text{rad}}(t, x)$ is a small component compared with $u_{\text{ab}}(t, x)$ describing deformation of the soliton shape and radiative losses.

An advantage of the adiabatic approximation is that it reduces a stochastic partial differential equation to a system of ordinary differential equations for the soliton parameters. For Equation (1), the adiabatic approximation corresponds to the substitution (5) with time-dependent coefficients $\eta(t)$, $\xi(t)$, $\mu(t)$, and $\beta(t)$. If $R[u] \equiv u(t, x)$, the standard perturbation theory for solitons shows that (Karpman, 1979)

$$\frac{d\mu}{dt} = \eta \int_{-\infty}^{\infty} \frac{\tanh z}{\cosh^2 z} \varepsilon \left(t, \frac{z}{\eta} + 2\xi \right) dz, \quad (12)$$

$$\frac{d\xi}{dt} = 2\mu, \quad \eta = \text{const}, \quad (13)$$

$$\frac{d\beta}{dt} = \mu^2 + \eta \int_{-\infty}^{\infty} \frac{1 - z \tanh z}{\cosh^2 z} \varepsilon \left(t, \frac{z}{\eta} + 2\xi \right) dz. \quad (14)$$

If $\varepsilon(t, x) = f(t)x$, one recovers the exact solution. As the perturbation is random, this is a system of stochastic equations; it allows rather complete analysis when $\varepsilon(t, x) \equiv V_\varepsilon(x)$ is an ergodic process with a finite support localized on the interval $[0, L/\varepsilon^2]$ (Garnier, 1998). The soliton dynamics are then governed by deterministic equations for almost every realization of $V_\varepsilon(x)$. For a soliton of small amplitude (weak nonlinearity), one can define $v_0 \ll \mu$ such that decay of the soliton amplitude follows either an exponential, for $v < v_0$, or a power, for $v_0 v \ll \mu$, law. When the soliton has large amplitude and small velocity, $\mu \ll v$, its amplitude experiences rather weak changes, while the velocity decreases.

Solitary Wave Propagation in Media with Fluctuating Parameters

Consider $\varepsilon(t, x) \equiv f(t)$ to be a stationary Gaussian process (4). Then the adiabatic approximation allows us to obtain a Fokker–Planck equation for the distribution function of the soliton parameters, similar to Equation (6), where typical behavior is a kind of Brownian motion (Konotop & Vázquez, 1994). At large times, the adiabatic approximation fails and fluctuations of the medium may result in resonant parametrical processes. Such processes are especially interesting in systems having topological solitons which cannot be destroyed by fluctuations. If, for example, $R[u] \equiv u - u^3$ in Equation (2), long-time numerical simulations of the kink dynamics show anomalous diffusion, and the dispersion of the fluctuation of its center grows as $t^{2.087}$ while the energy of the system increases exponentially. This phenomenon is a manifestation of the stochastic parametrical resonance of linear modes.

WAVE STABILITY AND INSTABILITY

As with other dynamic entities, a solution of a wave system is considered to be stable if it does not deviate greatly under small perturbations, and unstable if it does.

Consider first the stability of the null solution of a partial differential equation (PDE) system in an infinite and uniform medium. Small perturbations of the null solution can be taken in the form $A \exp[i(kx - \omega t)]$. To satisfy the PDE, k and ω are related by a dispersion relation, which is denoted as $D(k, \omega) = 0$.

The dispersion relation may be solved in the form

$$\omega = \omega_n(k), \quad (n = 1, 2, \dots). \quad (1)$$

Thus, there may be several solutions (or modes), with different functions $\omega_n(k)$, which are referred to as different modes. In general, ω may be complex for real k , leading to real solutions of the form

$$A \exp[i(kx - \omega t)] + \text{c.c.} \\ = \{A \exp[i(kx - \omega_r t)] + \text{c.c.}\} \exp(\omega_i t), \quad (2)$$

where $\omega = \omega_r + i\omega_i$. Therefore, if $\omega_i > 0$ for any mode, that mode will grow with time, indicating instability. If all ω_i are negative, all modes damp away, indicating stability.

Convective and Absolute Instability

In practice, an initial perturbation is often localized and can be represented as a (Fourier) wave packet of various normal modes, in which each component propagates with its own phase velocity ($v_p = \omega/k$). The collective motion of a wave packet, on the other hand, is governed by its group velocity ($v_g = d\omega/dk$). If a perturbative wave packet is localized and moving with a certain group velocity, its amplitude at a certain point will at first begin to rise and then eventually fall back to zero. This leads to two distinct concepts: convective and absolute instability, which originally arose in studies of wave instabilities in plasmas (Briggs, 1964).

A wave system is convectively unstable if the maximum amplitude of a perturbing wave packet grows without bound, but at any fixed point of the system, the disturbance eventually relaxes back to zero as the wave packet propagates away. Such behavior is useful for the design of distributed amplifiers, such as the traveling-wave tube or optical (laser) amplifiers.

If the dispersion equation contains unstable modes with zero group velocity, however, a more robust instability arises. In this case, called absolute instability, perturbations grow without bound at every point of the system. Absolutely unstable dynamics can be employed for the design of distributed oscillators (backward-wave oscillators, for example) but not distributed amplifiers.

Modulational Instability

Consider next the stability of a small amplitude component of a wave system, which is stable at infinitesimal amplitude. At finite amplitude, however, the wave is not necessarily stable against wave modulation, because the finite intensity of wave modifies the propagation properties of medium. In this case, a nonlinear dispersion relation that takes into account the finite intensity of wave may be written as $\omega = \omega(k, a)$, where a is the amplitude of wave. For a slowly modulated plane wave having a small but

finite amplitude, the frequency ω may be expressed approximately as

$$\omega(k, a) = \omega_0(k) + \alpha(k)a^2 + O(a^4). \quad (3)$$

(Odd terms in a are excluded from this formulation because they would imply different values of ω when a merely changes its algebraic sign.) Modulations on a linear and weakly nonlinear wave train can be described by the equations (Whitham, 1974)

$$\frac{\partial k}{\partial t} + \frac{\partial \omega}{\partial x} \doteq 0, \quad (4)$$

$$\frac{\partial a^2}{\partial t} + \frac{\partial}{\partial x} \left(\frac{\partial \omega}{\partial k} a^2 \right) \doteq 0. \quad (5)$$

Equation (4) follows from the relations $\omega = -\partial\theta/\partial t$ and $k = \partial\theta/\partial x$, where $\theta(x, t)$ is the phase. (This equation can also be viewed as a conservation law for wave crests.) As a^2 is proportional to energy density and $a^2\partial\omega/\partial k = a^2v_g$ is proportional to power flow, Equation (5) is the law of energy conservation.

Substituting Equation (3) into these equations and assuming a to be sufficiently small leads to the following equations:

$$\frac{\partial k}{\partial t} + v_g \frac{\partial k}{\partial x} + \alpha(k_0) \frac{\partial a^2}{\partial x} \doteq 0, \quad (6)$$

$$\frac{\partial a^2}{\partial t} + v_g' a^2 \frac{\partial k}{\partial x} + v_g \frac{\partial a^2}{\partial x} \doteq 0. \quad (7)$$

Here $v_g = d\omega_0(k_0)/dk_0$, the group velocity of the linear wave with wave number k_0 , and $v_g' = d^2\omega_0(k_0)/dk_0^2$. Linearizing k and a by

$$k = k_0 + \bar{k} \exp[i(Kx - \nu t)], \\ a = a_0 + \bar{a} \exp[i(Kx - \nu t)],$$

yields the modulational dispersion relation

$$\nu = K \left(v_g \pm \sqrt{\alpha a_0^2 v_g'} \right). \quad (8)$$

If $\alpha v_g' < 0$, ν becomes complex, which implies that the modulation becomes unstable and grows (Lighthill, 1965; Whitham, 1974). Equation (8) is called Lighthill's theorem, and the corresponding modulational instability (which has been studied analytically and experimentally in the context of deep water waves by Benjamin & Feir (1967)) is called the Benjamin–Feir (BF) instability. The nonlinear evolution of modulated envelopes is described by the nonlinear Schrödinger equation. Interestingly, the BF instability can lead to formation of stable traveling waves of modulation—envelope solitons. For further discussions, see Whitham (1974), Infeld & Rowlands (2000), Longuet-Higgins (1978), and McLean (1982).

Soliton Stability

The stability problem of traveling-wave solutions with respect to small perturbations has been studied by

various methods, including the normal-mode approach (Infeld and Rowlands, 2000). Consider the solution $u(x, t)$ of a nonlinear PDE to be the stationary traveling wave $u_s(\xi)$ plus a small perturbation $p(\xi, t)$

$$u(x, t) = u_s(\xi) + p(\xi, t), \quad (9)$$

where $\xi = x - v_s t$ and v_s is a propagation velocity. Transforming the original nonlinear PDE to a coordinate system moving at v_s and linearizing, the resulting equation has parameters that are functions of ξ . This equation can then be solved for the time development of the perturbation subject to an appropriate boundary condition.

When such problems are uniform in time (as they often are), it is convenient to express $p(\xi, t)$ as product solution in the form $p(\xi, t) = f(\xi) \exp(\sigma t)$ (separation of variables). Traveling-wave solutions are linearly unstable if any product solution has $\text{Re}(\sigma) > 0$ and asymptotically stable if all product solutions have $\text{Re}(\sigma) < 0$. A stationary solution that is neither unstable nor asymptotically stable is said to be neutrally stable, and there is always such a case because $\sigma = 0$ corresponds to a simple displacement of the traveling wave in the direction of propagation.

As examples, consider the stability of solitons of the Korteweg–de Vries (KdV) and its two-dimensional generalization. Writing the KdV equation as $u_t + 6(u^2)_x + u_{xxx} = 0$, a solitary wave solution is given by

$$u_s = A + k^2 \text{sech}^2\{k(x - v_s t) + \delta\} = 0, \quad (10)$$

where $v_s = 4k^2 + 12A$ and A and k are both arbitrary. Using the method of normal modes, Jeffrey and Kakutani (1972) and also Berryman (1976) have investigated the stability of this soliton, showing that small localized perturbations do not grow without bound; thus, the KdV soliton is linearly stable. Benjamin formulated a nonlinear stability theory for the KdV soliton and also showed that the KdV soliton is stable against small but finite perturbations (Benjamin, 1972).

A soliton in a two-dimensional (2-d) space often appears as a line soliton (LS). Kadomtsev and Petviashvili studied a 2-d-generalization of the KdV equation in order to discuss the stability of the line soliton with respect to long and small transverse perturbations. They obtained the KP equation (Kadomtsev & Petviashvili, 1970)

$$(u_t + 6(u^2)_x + u_{xxx})_x + s u_{yy} = 0, \quad (s = \pm 1), \quad (11)$$

which corresponds to the case of negative and positive dispersion when $s = +1$ and -1 , respectively. The line soliton is unstable in the case of positive dispersion and is stable for negative dispersion. The KP equation with positive dispersion also has a periodic soliton (PS) solution. A spatially periodic resonance exist between the LS and PS solutions, as indicated in Figure 1. From this

Figure 1. The sequence of snapshots of quasiresonant solution.

figure, we see how a transversely perturbed LS decays into a small LS and a PS, where the instability of the LS may be relaxed by the emission of a PS (Infeld and Rowlands, 2000, Chapter 10). Importantly, the nonlinear stage of instability of soliton is, in general, different from the conclusion of the linear stability theory. For more detailed studies of 2-d soliton stability, see Infeld & Rowlands (2000) and Zakharov et al. (1986).

Eckhaus Instability

In the neighborhood of a bifurcation (the appearance of a new solution as a parameter λ is changed), the description of a dynamical system can be greatly reduced, where the only relevant variable is a complex normalized amplitude: Z . Studies of the dissipative structures that emerge beyond the instability is often facilitated by using amplitude equations, such as the Newell–Whithead (NW) equation (Newell & Whitehead, 1969)

$$\frac{\partial Z}{\partial t} = (\lambda - \lambda_c)Z + \left(\frac{\partial}{\partial x} - \frac{i}{2k_c} \frac{\partial^2}{\partial y^2}\right)^2 Z - |Z|^2 Z.$$

(12)

This is the normal form of a symmetry-breaking bifurcation leading to roll or stripe patterns with wave

vector parallel to the x -axis, where λ_c is the critical control parameter and k_c is the critical wave number. In the supercritical region, $(\lambda - \lambda_c) > 0$, the NW equation has the two parameter $(\delta k, \theta_0)$ family of solutions:

$$Z_k = A_k e^{i(\delta k x + \theta_0)},$$

(13)

where $A_k = \sqrt{(\lambda - \lambda_c) - (\delta k)^2}$, δk is a small wave number describing the modulation of the basic dissipative structure at the critical wave number k_c , and θ_0 is an arbitrary phase. This solution expresses a stationary roll pattern with wave number $k = k_c + \delta k$.

Introducing a solution that is perturbed by small changes in amplitude and phase leads to the instability criterion (Eckhaus, 1965)

$$|\delta k| > \sqrt{\frac{\lambda - \lambda_c}{3}}.$$

(14)

If perturbations transverse to the basic structure are allowed, a zig-zag instability emerges (Nicolis, 1995; Mori & Kuramoto, 1998).

Nerve Impulse Stability

The stability of nerve impulses can be studied by the reduced version of the Hodgkin–Huxley system called the FitzHugh–Nagumo (FN) equation (FitzHugh, 1961; Nagumo et al., 1962):

$$\frac{\partial V}{\partial t} = \frac{\partial^2 V}{\partial x^2} - f(V) - R,$$

$$\frac{\partial R}{\partial t} = \varepsilon(V - bR),$$

where V is the nerve membrane potential, $f(V) = V(V - 1)(V - a)$, and ε is a temperature parameter which controls the rate of change of the recovery variable R .

If $0 < \varepsilon < \varepsilon_c$, the FN equation has slow and fast impulse solutions with propagation speeds $c_s(\varepsilon)$ and $c_f(\varepsilon)$: $0 < c_s < c_f$. The relation between these two speeds and the temperature parameter is sketched in Figure 2, where the fast solution is stable and the slow solution is unstable (Rinzel & Keller, 1973). Thus, small positive perturbations of the slow solution will eventually grow into the fast solution, whereas small negative perturbations will cause the slow solution to collapse to zero (Scott, 2003).

At each value of ε , the FN equation has also two periodic traveling-wave solutions with the same wavelength but different propagation speeds. Viewed as a traveling wave, the fast periodic solution is stable and the slow solution is unstable, just as for a single impulse.

Suppose that a time-periodic boundary condition is imposed at $x = 0$ (where $V(0, t) = V(0, t + T)$) and periodic solutions are sought (for $x > 0$) of the form $V(x, t) = V(x + \lambda, t) = V(x, t + T)$. In this “signaling problem,” an important question is whether (or not)

Figure 2. The typical relation between the pulse speed c and the temperature parameter ε .

small perturbations grow with x . Because $c(\lambda) = \lambda/T$, the dependence of the nonlinear frequency ($1/T$) upon the nonlinear wave number ($1/\lambda$) is readily calculated, and Rinzel has shown that the condition for solutions not to grow with increasing x is (Rinzel, 1975)

$$\frac{d(1/T)}{d(1/\lambda)} > 0.$$

WAVE TANKS

See **Laboratory models of nonlinear waves**

WAVELETS

The wavelet transform is a tool that divides up data, functions, or operators into different frequency components and then studies each component with a resolution matched to its scale. The idea emerged independently in many different fields, including mathematics, quantum physics, electrical engineering, and seismology. By the end of the 1980s, French researchers Grossmann & Morlet (1984), Meyer (1990), and later Daubechies (1992) had laid the mathematical foundations of the wavelet transform technique. Their work was motivated by the problem Morlet (a geophysicist) was facing while analyzing seismic data which comprised different features in time and frequency.

The frequency content of a signal can be obtained by taking its Fourier transform. However, in transforming to the frequency domain, time information is lost and it is impossible to tell when a particular event took place. To correct this deficiency, the Fourier transform was adapted to analyze only a small section (or window) of the signal at a time. Such a short-time Fourier transform (STFT) maps a signal into a two-dimensional function of time and frequency and provides information about both when and at what frequencies a signal event occurs. This information can only be obtained with limited precision, and that precision is determined by

the size of the time window. The main drawback of STFT is that once a particular size for the time window is chosen, that window is the same for all frequencies. With Morlet's data, this approach failed either to follow the time evolution of rapid events or to estimate the frequency content in the low-frequency band.

Wavelet analysis represents the next logical step: signal cutting is performed by a window of variable length. Short windows are used at high frequencies and long windows at low frequencies. Thus, the time-frequency resolution is no longer constant but changes with frequency, allowing good time resolution for high frequencies and good frequency resolution for low frequencies to be achieved.

In Fourier analysis, the signal is decomposed into sine waves of various frequencies. Similarly, wavelet analysis is a decomposition of a signal into a set of basis functions $\Psi_{s,\tau}(t)$ called wavelets

$$\hat{f}(s, \tau) = \int f(t) \Psi_{s,\tau}^* dt, \quad (1)$$

where $\hat{f}(s, \tau)$ is the wavelet transform of $f(t)$ and $*$ denotes complex conjugation. The wavelets are generated from a single basic wavelet $\psi(t)$ called the mother wavelet, by scaling and translation:

$$\Psi_{s,\tau} = \sqrt{|s|} \psi\left(\frac{t-\tau}{s}\right). \quad (2)$$

As the scaling parameter s changes, the wavelets cover different frequency ranges: large values of s correspond to low frequencies, small values of s correspond to high frequencies. Changing the translation parameter τ allows the time localization center to be moved: each $\Psi_{s,\tau}(t)$ is localized around $t = \tau$. The factor $\sqrt{|s|}$ is for energy normalization across different scales.

An important difference between wavelet and Fourier transforms is that wavelet basis functions are not specified. The theory deals with general properties of wavelets and defines a framework within which different wavelets can be designed. Numerous families of wavelets have been proposed and proven to be useful in different applications. In order for a function to be used as the mother wavelet, it must allow for analysis and reconstruction of the signal without loss of information. This so-called admissibility condition implies that the average value of a wavelet in the time domain must be zero and it must, therefore, be oscillatory, a wave. The other important property of wavelets (the regularity condition) states that wavelets are smooth and concentrated both in time and frequency. This makes them suitable for capturing local features of a signal. Figure 1 presents an example of a wavelet, the Morlet wavelet, in time and frequency domains for two scales.

We can distinguish between the continuous and discrete wavelet transform. In a continuous transform, the parameters s and τ vary continuously. It maps

a one-dimensional signal to a two-dimensional time-scale joint representation that is highly redundant. This redundancy can be either exploited or removed. To reduce the redundancy, discrete wavelets have been introduced, which can only be scaled and translated in discrete steps. For the scale, we choose integer powers of fixed dilation parameter $s_0 > 1$, $s = s_0^j$, and j is an integer. The discretization of the translation parameter τ depends on j : narrow wavelets are translated by small steps, while wider wavelets are translated by larger steps, $\tau = n\tau_0 s_0^j$, with j and n integers and $\tau_0 > 0$ is fixed. For some special choices of mother wavelets, the discrete wavelets can be made orthogonal to their own translations and dilations. In this case, they behave exactly like an orthonormal basis and redundancy is removed.

Wavelets have a bandpass-like spectrum and can be viewed as bandpass filters. Compression in time stretches the spectrum and shifts it upwards, while stretching in time compresses the bandwidth and shifts it toward zero (Figure 1). The series of dilated wavelets can be used to cover the spectrum of a signal. However, an infinite number of wavelets is needed to reach zero frequency. This problem was solved by introducing a low-pass or averaging filter with a spectrum that belongs to the scaling function $\phi(t)$. If we analyze the signal using a combination of scaling functions and wavelets, the scaling function takes care of the spectrum otherwise covered by all the wavelets up to a chosen scale, while the rest is done by wavelets. The family of scaling functions and wavelets allows for wavelet multiresolution analysis. In multiresolution analysis, the signal is split into an approximation on a coarser scale, obtained using the scaling function, and details on a current scale, obtained by wavelets. This process is repeated, giving a sequence of approximations and details removed at every scale. After N iterations, the original signal can be reconstructed by summing up the last approximations and details on all previous scales.

Interactions between the fields where wavelets were first introduced have led to many wavelet applications. Wavelets are of particular interest for the analysis of nonstationary signals with broad spectra because they permit time-frequency presentation with logarithmic resolution. Wavelet analysis is capable of revealing aspects of signals that other signal analysis techniques miss, such as trends, breakdown points, discontinuities in higher derivatives, and self-similarity. Furthermore, wavelet analysis can often compress (or reduce noise in) a signal without appreciable degradation. The above-described one-dimensional aspect can be generalized to more dimensions, for example, to handle image analysis. Wavelets are a very powerful tool for image compression, since wavelet transform clearly separates high-pass and low-pass information on a pixel-by-pixel

Figure 1. Morlet wavelet in time and frequency domain for scales $s = 1$ (a,b) and $s = 2$ (c,d).

basis. Among the successes of wavelet representation are the compression of digitized fingerprints by the US Federal Bureau of Investigation and image compression using the JPEG 2000 standard (the older JPEG standard uses a non-wavelet compression).

WINDING NUMBERS

If you wrap a rubber ring (rubber band) around a pencil, the intuitive idea of an integer invariant for the wrapping process arises. The number of oriented turns around the

pencil is an integer, and it is independent of how tight or creased the ring is. The only way to change this integer is to wrap/unwrap one loop of the ring at the endpoints of the pencil. Using a rubber string, the number of turns could be some real number instead.

How does this fact connect with dynamics? Consider a three-dimensional (3-d) dynamical system having a torus as phase space. Let the hole in the torus represent the pencil and the rubber ring represent a closed trajectory within the torus. Small modifications to the trajectory will not alter the wrapping property.

The underlying feature in the above examples is the forbidden region given by the pencil or the hole of the torus. To further analyze its structure, decompose 3-d space ($\mathbb{R}^3$) as the product of the pencil direction times a perpendicular plane (equivalent to $\mathbb{R}^2$). The role of the pencil is to identify a special point on that plane given by the projection along the pencil direction.

Similarly, consider a periodic orbit in $\mathbb{R}^3$, as the forbidden region. Since the points in the periodic orbit are regular points in a small tube around the periodic orbit, the flow can be decomposed in a component parallel to the periodic orbit and a projected flow onto a perpendicular section. Hence, any other closed trajectory sufficiently near to the orbit will wind around it. A similar situation arises around a period-one orbit of a periodically forced flow in $\mathbb{R}^2$.

The winding number characterizes the topological properties of “the plane minus one point.” Moreover, the topology of the plane minus n points gives a deeper characterization of the periodic orbit structure of 3-d dynamical systems admitting a Poincaré section.

Definition

Consider a simple continuous closed curve γ in the complex plane ($\mathbb{C}$) and a point $z_0 \in \mathbb{C} - \gamma$. The winding number n is defined as

$$n(\gamma, z_0) = \frac{1}{2\pi i} \int_{\gamma} \frac{dz}{z - z_0}. \tag{1}$$

We may regard our wrapped rubber ring as a suitable complex function γ of the unit circle, thus connecting our motivating idea with the formal definition (similarly for the second example if we project the torus along the direction perpendicular to the hole when seen as a disc). Where appropriate in the sequel, we will let $z_0 = 0$ for simplicity and recast γ as a map of the unit circle $\gamma : \mathbb{S}^1 \rightarrow \mathbb{S}^1$. It follows from Equation (1) that $n(\gamma, 0)$ is a real integer given by

$$n(\gamma, 0) = \int_{\mathbb{S}^1} \frac{\gamma'(\theta)}{\gamma(\theta)} d\theta, \tag{2}$$

which is called the degree of γ (Rotman, 1988, p. 50).

Applications

Homotopy classes of the circle. A loop is a continuous map g of the circle to itself such that $g(0) = g(2\pi) = 2\pi$. Two loops α and β are homotopic if there exists a continuous map $H : \mathbb{S}^1 \times [0, 1] \rightarrow \mathbb{S}^1$ such that $H(\cdot, 0) = \alpha$, $H(\cdot, 1) = \beta$ and for each t , $H(\cdot, t)$ is a loop. In other words, two loops are homotopic if one can continuously deform one of them into the other, keeping it as a loop all the way throughout the deformation. The winding number classifies the homotopy classes of loops, namely, if σ is homotopic to γ , then $n(\sigma, 0) = n(\gamma, 0)$ (Rotman, 1988, p. 52).

Braids and periodic orbits. While the plane minus one point produces the winding number as a class invariant under homotopies, the homotopy classes of the plane with n special points requires a more elaborated structure which connects nicely with the dynamical properties of 3-d flows admitting a Poincaré section. In fact, periodic orbits of such flows can be regarded as imbeddings of the unit disk in phase space parametrized with time in units of $2\pi/T$ where T is the minimal period. On the Poincaré section, these special trajectories appear as an invariant set of n periodic points. The homotopy classes of loops on the plane with an invariant set of n points are classified by elements of the *Braid group on n strands* (Thurston, 1988; Hall, 1994; Natiello & Solari, 1994).

Linking number. In the same lines, given a pair of periodic orbits in phase space, we may think of the number of turns that one orbit does around the other when completing one excursion along itself. Such number is a link invariant which has a natural interpretation in terms of winding number, and it is called *linking number* (Uezu & Aizawa, 1982; Solari et al., 1996).

For 3-d flows admitting a Poincaré section, the periods of the orbits are commensurate and one may compute the average rotation per period of one orbit around another. This is called the *relative rotation rate* (Solari et al., 1996) and helps in understanding the orbit organization of such flows.

Poincaré index (PI). Consider a planar dynamical system $\dot{x} = f(x, y)$, $\dot{y} = g(x, y)$ and a simple closed counterclockwise curve C not passing through any equilibrium points. The PI k computed along C is defined as

$$\begin{aligned} k &= \frac{1}{2\pi} \int_C d \left\{ \arctan \left(\frac{dy}{dx} \right) \right\} \\ &= \frac{1}{2\pi} \int_C \frac{f dg - g df}{f^2 + g^2}. \end{aligned} \tag{3}$$

(See below for a discussion of the PI in terms of complex analysis and winding number.)

In the context of planar dynamics, the PI of a node or a center is $+1$, of a hyperbolic saddle point is -1 , and of a closed orbit is $+1$. Also the PI of a closed

curve not containing fixed points is zero, and the PI of a closed curve equals the sum of the indices of the fixed points within (Guckenheimer & Holmes, 1983, p. 51).

Fixed point theorems. The degree of a map can be generalized to higher dimensions. In fact, this property (or the winding number when adequate) is a basic ingredient in the proof of Brouwer's fixed point theorem. An interesting discussion of this fact along with some philosophical considerations can be found in www.mathpages.com.

Complex analysis. The computation of the winding number is a standard tool in the proof of the Fundamental Theorem of Algebra.

Also, let C be a closed contour on the complex plane not passing through any singularities or zeroes of the complex function f , which is analytic inside C except at most at a finite number of poles. Then

$$\frac{1}{2\pi i} \int_C \frac{f'(z)}{f(z)} dz = N - P, \quad (4)$$

where N is the number of zeroes of f and P the number of poles inside C . This is called the Principle of the Argument in standard textbooks (Wunsch, 1994, p. 458).

This result is related to Equation 2 and to the PI. Concerning Equation (2), taking the special point of the plane to be the origin (or any point inside the unit circle), n counts how many turns γ performs around this point when running along the unit circle. Assume now that f has only one zero inside C with multiplicity n and no poles. Then f restricted to C is exactly the same as γ with a suitable choice of parametrization for C and $\mathbb{S}^1$. Concerning the PI, let $z = x + iy$ and $F(z) = f(x, y) + ig(x, y)$, regarding

the xy -plane as the complex plane. If the vector field (f, g) is continuous, F will not have poles within C and the Poincaré index reduces to the Principle of the Argument calculation for F .

YANG–BAXTER EQUATION

See **Quantum inverse scattering method**

YANG–MILLS THEORY

Modern particle theories, such as the Standard Model, are quantum Yang–Mills theories. In a quantum field theory, space-time fields with relativistic field equations are quantized and, in many calculations, the quanta of the fields are interpreted as particles. In a Yang–Mills theory, these fields have an internal symmetry: they are acted on by space-time-dependent non-abelian group transformations in a way that leaves physical quantities, such as the action, invariant. These transformations are known as local gauge transformations, and Yang–Mills theories are also known as non-abelian gauge theories.

Yang–Mills theories, and especially quantum Yang–Mills theories, have many subtle and surprising properties and are still not fully understood, either in terms of their mathematical foundations or in terms of their physical predictions. However, the importance of Yang–Mills theory is clear; the Standard Model has produced calculations of amazing accuracy in particle physics, and in mathematics, ideas arising from Yang–Mills theory and from quantum field theory are increasingly important in geometry, algebra, and analysis.

Consider a complex doublet scalar field ϕ_a ; a scalar field is one that has no Lorentz index, but, as a doublet, ϕ_a transforms under a representation of $SU(2)$, the group represented by special unitary 2×2 matrices:

$$\phi_a(x) \rightarrow g_{ab}\phi_b(x), \quad (1)$$

where $g \in SU(2)$ and the repeated index are summed over. If this is a global transformation; that is, if g is independent of x , then derivatives of ϕ_a have the same transformation property as ϕ_a itself:

$$\frac{\partial \phi_a}{\partial x_\mu} \rightarrow \frac{\partial g_{ab}\phi_b}{\partial x_\mu} = g_{ab} \frac{\partial \phi_b}{\partial x_\mu} \quad (2)$$

However, this is not true for a local, or space-time-dependent, transformations where

$$\frac{\partial \phi_a}{\partial x_\mu} \rightarrow \frac{\partial g_{ab}\phi_b}{\partial x_\mu} = g_{ab} \frac{\partial \phi_b}{\partial x_\mu} + \frac{\partial g_{ab}}{\partial x_\mu} \phi_b. \quad (3)$$

In order to construct an action that includes derivatives and that is invariant under local transformations, a new derivative is defined that transforms the same way as ϕ_a :

$$D_\mu \phi_a = \frac{\partial \phi_a}{\partial x_\mu} + (A_\mu)_{ab} \phi_b, \quad (4)$$

where A_μ is a new two-indexed space-time field, called a gauge field or gauge potential, defined to have the transformation property

$$(A_\mu)_{ab} \rightarrow g_{ac}(A_\mu)_{cd}g_{db}^{-1} - \frac{\partial g_{ac}}{\partial x_\mu} g_{cb}^{-1}. \quad (5)$$

Now, under a local transformation

$$D_\mu \phi_a \rightarrow g_{ab} D_\mu \phi_b \quad (6)$$

and so, $D_\mu \phi_a$ transforms in the same way as ϕ_a . This derivative is called a covariant derivative.

A physical theory that includes the gauge field A_μ should treat A_μ as a dynamical field, and so the action should have a kinetic term for A_μ . In other words, the action should include derivative terms for A_μ . These terms are found in the field strength

$$F_{\mu\nu} = \frac{\partial A_\nu}{\partial x^\mu} - \frac{\partial A_\mu}{\partial x^\nu} + [A_\mu, A_\nu] \quad (7)$$

that has the covariant transformation property

$$(F_{\mu\nu})_{ab} \rightarrow g_{ac}(F_{\mu\nu})_{cd}g_{db}^{-1}, \quad (8)$$

where $[A_\mu, A_\mu]$ is the normal matrix commutator. In fact, the simplest Yang–Mills theory is pure Yang–Mills theory with action

$$S[A] = -\frac{1}{2} \int d^4x \text{trace } F_{\mu\nu} F^{\mu\nu} \quad (9)$$

and corresponding field equation

$$\frac{\partial F_{\mu\nu}}{\partial x_\mu} = 0. \quad (10)$$

Solutions to this equation are known as instantons (*See Instantons*).

More generally, Yang–Mills theories contain gauge fields and matter fields like ϕ and fields with both group and Lorentz or spinor indices. Also, the group action described here can be generalized to other groups and to other representations. In the case of the Standard Model of particle physics, the gauge group is $SU(3) \times SU(2) \times U(1)$, and the group representation structure is quite intricate.

Yang–Mills theory was first discovered in the 1950s. At that time, quantum electrodynamics (QED) was known to describe electromagnetism. Quantum electrodynamics is a local gauge theory but with an abelian gauge group. It was also known that there is an approximate global non-abelian symmetry called isospin symmetry that acts on the proton and neutron fields as a doublet and on the pion fields as a triplet. This suggested that a local version of the isospin symmetry might give a quantum field theory for the strong force with the pion's fields as gauge fields (O'Raifeartaigh, 1997). This did not work because pion fields are massive whereas gauge fields are massless, and the main thrust of theoretical effort in the 1950s and 1960s was directed at other models of particle physics.

However, it is now known that the proton, neutron, and pion are not fundamental particles, but are composed of quarks and that there is, in fact, a quantum Yang–Mills theory of the strong force with quark fields and gauge particles called gluons. Furthermore, it is now known that it is possible to introduce a particle, called a Higgs boson, to break the non-abelian gauge symmetry in the physics of a symmetric action and give mass terms for gauge fields. This mechanism is part of the Weinberg–Salam model, a quantum Yang–Mills theory of the electroweak force, that is a component of the Standard Model and that includes both massive and massless gauge particles.

These theories were only discovered after several key experimental and theoretical breakthroughs in the late 1960s and early 1970s. After it became clear from collider experiments that protons have a substructure, theoretical study of the distance-dependent properties of quantum Yang–Mills theory led to the discovery that Yang–Mills fields are asymptotically free (Gross, 1999). This means that the high-energy behavior of Yang–Mills fields includes the particle-like properties seen in experiments, but the low-energy behavior may be quite different, and in fact, the quantum behavior might not be easily deduced from the classical action. Confinement and the mass gap are examples of this. The strong force is a local gauge theory with quark fields. The quark structure of particles is observed in

collider experiments; but free quarks are never detected, instead, at low energies, they appear to bind together to form composite particles, such as neutrons, protons, and pions. This is called confinement. It is possible to observe this behavior in simulations of the quantum gauge theory of the strong force, but it has not been possible to prove mathematically that confinement is a consequence of the theory. The same is true of the mass gap; it is known that particles have nonzero mass, and this is observed in simulations, but there is no known way of deriving the mass gap mathematically from the original theory (Clay, 2002).

The symmetries of Yang–Mills theory can be extended to include a global symmetry between the bosonic and fermionic fields called supersymmetry. While there is no direct evidence for supersymmetry in physics, the indirect case is very persuasive, and it is commonly believed that direct evidence will be found in the future. Often, supersymmetric theories are more tractable; for example, Seiberg and Witten have found an exact formula for many quantum properties in $N = 2$ super-Yang–Mills theory (Seiberg & Witten, 1994). It is also commonly believed by theoretical physicists that the quantum Yang–Mills theories in particle physics are in fact a limit of a more fundamental string theory.

ZAKHAROV-SHABAT EQUATION

See Nonlinear Schrödinger equations

ZELDOVICH-FRANK-KAMENETSKY EQUATION

In 1938, Yakov Zeldovich and David Frank-Kamenetsky published a brief theoretical paper devoted to flame propagation, presenting one of the first nonlinear traveling-wave front solutions (Zeldovich & Frank-Kamenetsky, 1938). Although both scientists later played outstanding roles in Soviet H-bomb and nuclear projects (and then both performed remarkable works in different fields of physics, including the theory of elementary particles, plasma physics, astrophysics, and cosmology), in the third decade of the last century, they were engaged with the theory of combustion and detonation and attendant problems of chemical kinetics. Their paper was intended for experts and had a rather specialized character, but one of the problems that they examined can be presented as follows.

Consider the autocatalytic production, destruction, and diffusion transfer of a substance proceeding in a homogeneous active chemical medium that occupies some region of physical space. Such processes obey two fundamental macroscopic relationships, the continuity equation

$$u_t + \operatorname{div} \mathbf{J} = f(u)$$

and the phenomenological Fick diffusion law

$$\mathbf{J} = -D \operatorname{grad} u \quad (D = \text{const}).$$

Here, $u = u(\mathbf{r}, t)$ is the concentration of the substance at the point $\mathbf{r} = \{x, y, z\}$ and moment of time t ; the literal subscripts symbolize the derivatives with respect to the corresponding variables; the symbols div and grad designate the spatial divergence and gradient operators; $\mathbf{J} = \mathbf{J}(\mathbf{r}, t)$ is the vector of diffusion flux density of the substance; the function $f(u)$ is the kinetic function of the active medium, which determines the dependence of the production/destruction rate of

substance per unit volume on the concentration u ; and D is diffusivity.

Generally speaking, in a medium of this type, self-sustaining nonlinear concentration waves can propagate, and their velocities will not be arbitrary but will be determined by the balance between two types of processes: the active processes of production/destruction of a substance at each local patch of medium and the passive processes of diffusion transfer between the patches. With the diffusivity taken as unity (this can always be achieved by a proper choice of units of measurements), the wave velocity will depend only on the parameters of the function $f(u)$. The problem consists in finding both the profile of a propagating wave and the wave velocity.

Zeldovich and Frank-Kamenetsky solved the last problem for the case of a one-dimensional infinite medium extending along the x -axis, whose kinetic function is described by a cubic polynomial with three zeros (see below). In this case, the diffusion flux density $\mathbf{J}$ has only one nonzero component, the x -component J , and the two equations written above look (at $D = 1$) like

$$u_t + J_x = f(u),$$

$$J = -u_x,$$

or, equivalently,

$$u_t = u_{xx} + f(u), \quad (1)$$

where $f(u)$ is given as

$$f(u) = -Ku(u-b)(u-1), \quad (2)$$

where K is a positive constant and b is a constant ($0 < b < 1$). The reaction-diffusion equation (1) endowed with the kinetic function (2) is referred today to as the Zeldovich-Frank-Kamenetsky (ZF) equation. As its authors have noted, the cubic polynomial structure of (2) corresponds to autocatalysis of the second order.

The active chemical medium described by the ZF equation is bistable: it has two homogeneous stable

states described by two trivial solutions $u(x, t) \equiv 0$, $u(x, t) \equiv 1$ of Equation (1), which are determined by zeros $u=0, 1$ of the kinetic function (2). Its third homogeneous state $u(x, t) \equiv b$, which is determined by intermediate zero b of $f(u)$ and located between 0 and 1, is unstable; it plays the role of a threshold. Testing the stability of these states proceeds as follows.

Let $u = u_*$, $u_* \in \{0, b, 1\}$ be a coordinate of one of three zeros of the kinetic function, and $k_* = f_u(u_*)$, $k_* \in \{k_0, k_b, k_1\}$ be the slope of the kinetic function at this zero; note that the values of k_* satisfy the inequalities

$$\begin{aligned} k_0 &= f_u(0) = -Kb < 0, \\ k_b &= f_u(b) = Kb(1-b) > 0, \\ k_1 &= f_u(1) = -K(1-b) < 0. \end{aligned}$$

Next, find the solution to Equation (1) in form of $u(x, t) = u_* + w(x, t)$, where

$$\begin{aligned} w(x, t) &= \omega(x, t) \exp(k_* t) \\ w(x, 0) &= \omega(x, 0) = w_0(x), \\ |w_0(x)| &\ll 1 \end{aligned}$$

is the perturbation, supposed to be small at moments of time close to $t=0$. Substituting these expressions into (1) and linearizing the kinetic function, one comes to the usual diffusion equation $\omega_t = \omega_{xx}$. The solution of the latter, defining on the infinite x -axis and satisfying the initial condition $\omega(x, 0) = w_0(x)$ is well known to be given by Poisson's formula. Recopying this solution and multiplying it by the factor $\exp(k_* t)$ yields the expression

$$\begin{aligned} w(x, t) &= 2^{-1} (\pi t)^{-1/2} \exp(k_* t) \\ &\times \int_{-\infty}^{+\infty} \exp\left[-(x-x')^2/4t\right] w_0(x') dx', \end{aligned}$$

which describes the time evolution of perturbation. Examination of this expression indicates that $w(x, t)$ decreases with time at the values $k_* = k_0 < 0$ and $k_* = k_1 < 0$, that is, near the states determined by zeros 0, 1 of function $f(u)$. At $k_* = k_b > 0$ (near the state determined by intermediate zero b of function $f(u)$), the perturbation increases because the exponent below the integral rises with time faster than the preexponential factor $2^{-1} (\pi t)^{-1/2}$ falls.

For physical reasons, a bistable medium obeying the ZF equation must maintain the propagation of nonlinear wave fronts, which switch the medium from one of its two stable states to the other. For example, a wave of this type can be obtained numerically by setting the initial conditions $u(x, 0) = 1$ at $x < 0$, $u(x, 0) = 0$ at $x > 0$. In the steady-state regime, which is established after some transition time, the switching wave moves along x with constant velocity v and possesses a steady spatial profile, which is described by the traveling-wave front solution of a ZF equation of the kind

$$u = u(\xi), \quad \xi = x - vt, \quad (3)$$

$$u(-\infty) = 1, \quad u(+\infty) = 0, \quad (4)$$

$$|u(\xi)| < \infty. \quad (5)$$

Obtaining this solution is a principal goal of the ZF analysis. It includes both the problem of derivation of $u(\xi)$ and the relevant problem of determination of v . Of course, the latter problem is a central one: as a rule, it appears every time when one deals with wave propagation in nonlinear reaction-diffusion systems. Zeldovich and Frank-Kamenetsky found the expression for v in the case of (1), (2) to be

$$v = \sqrt{K/2}(1-2b) = \sqrt{2K}(1/2-b). \quad (6)$$

This beautiful formula connects the wave front velocity v with the position b of intermediate zero of the cubic kinetic function. In particular, it indicates that v is proportional to the deviation of b from the middle value of u , which is equal to $1/2$. If $b < 1/2$ ($b > 1/2$), then v is positive (negative), and the wave front, which obeys the boundary conditions (4), (5), moves in the positive (negative) direction of the x -axis. If b is exactly equal to $1/2$, then the front does not move: it is stationary.

A short derivation of (6) along with the expression for $u(\xi)$ proceeds as follows. First, substituting (3) directly into two equations written immediately before (1) (they are evidently equivalent to (1)) and allowing for the relations $\partial/\partial t = -v(d/d\xi)$, $\partial/\partial x = d/d\xi$, which follow from (3), one obtains

$$u_\xi = -J, \quad (7a)$$

$$J_\xi = -vJ + f(u). \quad (7b)$$

Second, dividing (7b) by (7a), one excludes the independent variable (thereupon, the evident equality $J_\xi/u_\xi = J_u$ is used) and reduces Equation (7) to the single equation

$$J J_u = vJ - f(u). \quad (8)$$

To be integrated correctly, this differential equation must be provided with the proper boundary conditions at the points $u=0, 1$, that is, in the equilibrium states that are achieved by the traveling wave front solution at $\xi \rightarrow \pm \infty$. To set these conditions, one should know the asymptotic behavior of diffusion flux $J = u_\xi(\xi)$ generated by the traveling wave near the states $u=0, 1$. To recognize it, one represents the unknown solution near these states in the form of $u(\xi) = u_* + w(\xi)$, $u_* \in \{0, 1\}$, where $w(\xi)$ is a small perturbation necessarily satisfying the conditions $w(\pm\infty) = 0$. Substituting this expression directly into (1) and linearizing the kinetic function yields

$$w \xi \xi + v w \xi - |k_*| w = 0, \quad (k_* = f_u(u_*),$$

$$k_* \in \{k_0, k_1\}, k_0 < 0, k_1 < 0),$$

where the negative parameter k_* is presented as the positive constant $|k_*|$ taken with the sign "minus." The

solutions of the last linear ordinary equation, singled out by the conditions $w(\pm\infty) = 0$ look like

$$w = A_1 \exp(\lambda_1 \xi), \quad A_1 = \text{const}, \\ \lambda_1 = -(v/2) + \sqrt{(v/2)^2 + |k_*|} > 0 \\ (\text{at } \xi \longrightarrow -\infty),$$

$$w = A_2 \exp(\lambda_2 \xi), \quad A_2 = \text{const}, \\ \lambda_2 = -(v/2) - \sqrt{(v/2)^2 + |k_*|} < 0 \\ (\text{at } \xi \longrightarrow +\infty).$$

Thus, irrespective of the unknown value of velocity v , the traveling-wave front solution $u(\xi)$ approaches its limit values 0, 1 exponentially and therefore, the diffusion flux $J = -u_\xi = -w_\xi$ tends to zero near these values. Hence, the correct boundary conditions to the solution $J(u)$ of Equation (8), which are compatible with the desired traveling wave front solution (3)–(5), look like

$$J(0) = J(1) = 0. \quad (9)$$

Next, Zeldovich and Frank-Kamenetsky assumed the solution to Equation (8) to have the form of a quadratic parabola $J = -\alpha u(u-1)$ (α is a positive constant to be determined), which satisfies conditions (9) automatically. Substituting this expression into (8) and performing the cancellation yields an equation of the sort $P(\alpha, v)u + Q(\alpha, v) = 0$, where $P(\alpha, v)$ and $Q(\alpha, v)$ are set by calculations. Here, u can take any value belonging to the segment $[0, 1]$. Fixing the variable u on its limit value $u=0$ yields the equation $Q(\alpha, v) = 0$; taking into account the latter and setting $u=1$ yields the equation $P(\alpha, v) = 0$. Solving these two equations with respect to α and v leads directly to Equation (6) and to the desired expression $J = -\sqrt{K/2}u(u-1)$. Substituting the latter into (7a) and taking the integral (at the condition $u(0) = \frac{1}{2}$) yields the desired profile of the traveling-wave front:

$$u = 1 / \left[1 + \exp \left(\sqrt{K/2} \xi \right) \right] \\ = (1/2) \left[1 - \tanh \left(\sqrt{K/8} \xi \right) \right]. \quad (10)$$

To appreciate the significance of this result in the context of current knowledge, we should stress that the problem of finding a traveling-wave solution to the parabolic reaction-diffusion equations dramatically differs from that arising in the case of nonlinear hyperbolic equations. The latter correspond to conservative physical systems and usually possess the first integrals of the kind of integrals describing energy conservation. Such equations have a Hamiltonian structure, which helps to integrate them analytically using different powerful methods (for example, by methods based on the

inverse scattering problem). But the ZF equation is dissipative rather than conservative. Thus it is not Hamiltonian: it describes a gradient physical system that shows the dissipation of its free energy during its time evolution. In these circumstances, the analytical integration of reaction-diffusion equation (1) with the arbitrary kinetic function was a challenge. Zeldovich and Frank-Kamenetsky were the first to have recognized the integrable case of this equation and presented its nontrivial solution.

We should emphasize a distinction of the ZF equation from Fisher's equation, which was investigated in 1937, one year before Zeldovich and Frank-Kamenetsky's work.

The form of the Fisher equation is identical to (1), but the corresponding kinetic function is a quadratic polynomial, which possesses only two zeros. Of course, these zeros correspond to two stationary states of an active medium, but only one of them is a stable one, whereas the second is unstable. As a consequence, the Fisher equation admits not only one traveling-wave front solution, but also a continuum of such waves, and either of them is very responsive to the initial conditions. This equation is applicable only to those media in which the processes of spontaneous production of substances occur against the unstable background state.

In contrast to the Fisher equation, the ZF equation describes active media, which possess two stable states, separated by a third, unstable, state playing the role of a threshold of excitation. The natural field of application of the ZF equation covers the class of bistable active media displaying threshold properties. The linear stability analysis, which was first carried out by Zeldovich and Barenblatt in 1959, and subsequent nonlinear stability analyses performed independently by Lingren and Buratti and by Maginu show that traveling-wave fronts propagating in such media are stable (Scott, 2002).

After Zeldovich and Frank-Kamenetsky's work, decades passed before new analytical traveling-wave front solutions to the ZF-like reaction-diffusion equations appeared. They were constructed with the use of different representations of three-zero kinetic function including the piecewise linear and sinusoidal approximations (Scott, 2002, 2003). The significance of these solutions is predetermined by the fact that all of them describe various physical, chemical, and biological phenomena, which, at first glance, have no common ground. Among these are:

- Electric signals propagating along bistable transmission lines of nerve fibers and neuristors (Scott, 2002, 2003);
- Thermal waves switching boiling regimes from nucleate to film boiling near one-dimensional fuel elements (Zhukov et al., 1980);

- Waves of resistance modification in normal metals (Barelko et al., 1983) and superconductors (Gurevich & Mints, 1984), caused by thermal change;
- Gene flows and population waves in spatially distributed biological populations (Svirezhev & Pasekov, 1990) and
- Nonlinear processes arising in synergetics (Loskutov & Mikhailov, 1996).

In view of these applications, the importance of Zeldovich and Frank-Kamenetsky's result is established, yet the destiny of their paper of 1938 is strange. The result obtained in it was used in the Soviet Union for processing experimental data on chemical kinetics even before World War II. After the war, when rapid development of research in the field of physiology of nervous impulses and nonlinear physical chemistry took place, Equation (6) for the velocity of a traveling-wave front became familiar to a broad audience of researchers and appeared frequently in papers and monographs. But the manuscript from which this formula was derived for the first time seemed to have been forgotten: the paper has not been cited until recently! Surprisingly, it is absent even in the two-volume edition of Zeldovich's selected works issued in Russia in 1984, in the lifetime of their author. However, as Mikhail Bulgakov has written (in his classic *Master and Margarita*): "manuscripts do not burn." One could add: even if they are devoted to the theory of combustion.

ZERO-DISPERSION LIMITS

The Korteweg–de Vries (KdV) equation with small dispersion

$$\begin{cases} u_t - uu_x + \varepsilon^2 u_{xxx} = 0, & t, x \in R, \\ u(x, t = 0; \varepsilon) = u_0(x), \end{cases} \quad (1)$$

is a model for the formation and propagation of dispersive shock waves in one dimension. Let $u(x, t; \varepsilon)$ denote the solution of Cauchy problem (1), where the initial data $u_0(x)$ is smooth and decreases at infinity sufficiently fast. It is known that for $\varepsilon > 0$, no matter how small, the solution of (1) remains smooth for all $t > 0$. For $\varepsilon = 0$, (1) becomes the Cauchy problem for the Hopf equation

$$\begin{cases} u_t - uu_x = 0, \\ u(x, t = 0) = u_0(x). \end{cases} \quad (2)$$

The solution of the Hopf equation can be obtained by the method of characteristics. If the initial data $u_0(x)$ is somewhere increasing, the solution $u(x, t)$ of Equation (2) always has a point (x_c, t_c) of gradient catastrophe where an infinite derivative develops.

After the time of gradient catastrophe t_c , the solution $u(x, t, \varepsilon)$ of (1) develops in the neighborhood of x_c an expanding region filled with rapid modulated oscillations of wavelength of order $1/\varepsilon$. These oscillations are called dispersive shock waves.

Lax and Levermore (1998), performing the zero-dispersion asymptotics for the inverse-scattering problem for the KdV equation, showed that as ε tends to zero, $u(x, t; \varepsilon)$ tends uniformly to the smooth solution $u(x, t)$ of (2) as long as $t < t_c$. For $t > t_c$, the solution $u(x, t; \varepsilon)$ converges weakly in the oscillation region to a limit $\bar{u}(x, t)$ that is not a solution of conservation law (2).

The first example describing dispersive shock waves was proposed by Gurevich and Pitaevski (1973). Their description was rigorously proved by Venakides (1990) who derived the general form of the rapid oscillations. The oscillation zone is approximately described for a short time $t > t_c$ by a modulated periodic wave solution

of the KdV equation:

$$u(x, t, \varepsilon) \simeq V(x, t) + \frac{1}{3}\alpha(x, t) + \Theta\left(\frac{x - Vt + \phi}{\varepsilon}\right), \quad (3)$$

$$V(x, t) = \frac{1}{6}(u_1(x, t) + u_2(x, t) + u_3(x, t)).$$

In the above formula, the term $V(x, t) + \frac{1}{3}\alpha(x, t)$ is the weak limit $\bar{u}(x, t)$ of $u(x, t, \varepsilon)$ as $\varepsilon \rightarrow 0$, while the remaining term describes the rapid oscillations. The function Θ is 2π -periodic with zero average, and it can be expressed in terms of elliptic functions. The quantity α defined below and the phase ϕ depend on some functions $u_i(x, t)$, $i = 1, 2, 3$. The functions $u_1(x, t) > u_2(x, t) > u_3(x, t)$ solve the Whitham (1974) modulation equations

$$\begin{aligned} \partial_t u_i(x, t) - \lambda_i(u_1, u_2, u_3) \partial_x u_i(x, t) &= 0, \\ i &= 1, 2, 3, \end{aligned} \quad (4)$$

where

$$\begin{aligned} \lambda_i(u_1, u_2, u_3) &= \frac{1}{3}(u_1 + u_2 + u_3) \\ &+ \frac{2 \prod_{j \neq i, j=1}^3 (u_i - u_j)}{u_i + \alpha}, \end{aligned} \quad (5)$$

$$\alpha = -u_3 + (u_3 - u_1) \frac{E(s)}{K(s)} \quad (6)$$

and $K(s)$ and $E(s)$ are the complete elliptic integrals of the first and second kind with modulus $s = (u_2 - u_1)/(u_3 - u_1)$.

The solution $u_1(x, t) > u_2(x, t) > u_3(x, t)$ of the Whitham equations can be plotted in the (x, u) plane as branches of a multivalued function. The solutions of the Hopf equation and the Whitham equations are connected to one another as illustrated in Figure 1(a). The function $u_2(x, t)$ can vary from $u_3(x, t)$ to $u_1(x, t)$. On the $(x, t \geq 0)$ plane, the oscillation region is bounded on one side by the curve $x^-(t)$ where $u_2(x, t) = u_1(x, t)$, and on the other side by the curve $x^+(t)$ where $u_2(x, t) = u_3(x, t)$ (see Figure 1(a)). For $x^-(t) < x < x^+(t)$, the solution of (1) for small ε is approximately given by (3) while outside the interval $[x^-(t), x^+(t)]$ is given by the solution $u(x, t)$ of the Hopf equation (2). At edge $x = x^-(t)$ of the oscillation region, the amplitude of the oscillations vanishes and (3) goes to $u(x, t, \varepsilon)|_{u_1=u_2} \simeq u_3(x, t)$. When $x = x^+(t)$, solution (3) goes to the one-soliton solution of the KdV equation. In general, the oscillation zone grows with time. For generic analytic initial data with a cubic inflection point, the growth in the (x, t) plane of the oscillation zone near the point of gradient catastrophe (x_c, t_c) is described, up to shifts and rescaling, by the semi-cubic law

$$x^\pm(t) = x_c \pm a^\pm (t - t_c)^{3/2},$$

Figure 1. (a) The dashed line represents the formal solution of the Hopf equation; the continuous line represents the solution of the Whitham equations. The solution $(u_1(x, t), u_2(x, t), u_3(x, t))$ of the Whitham equations and the position of the boundaries $x^-(t)$ and $x^+(t)$ are to be determined from the conditions $u(x^-(t), t) = u_3(x^-(t), t)$, $u(x^+(t), t) = u_1(x^+(t), t)$, where $u(x, t)$ is the solution of the Hopf equation. (b) The oscillations in the region $x^-(t_1) < x < x^+(t_1)$.

where $a^\pm$ are two positive numbers. A completely different behavior appears in the zero-diffusion case. The simplest equation that combines nonlinearity and diffusion is the Burgers equation

$$u_t - uu_x = \varepsilon u_{xx}, \quad (7)$$

where $\varepsilon > 0$. For smooth initial data $u_0(x)$, the Burgers equation can be integrated through the Cole–Hopf transformation to

$$u(x, t, \varepsilon) = -\frac{\int_{-\infty}^{\infty} \frac{x-\xi}{t} e^{-\frac{G(\xi)}{2\varepsilon}} d\xi}{\int_{-\infty}^{\infty} e^{-\frac{G(\xi)}{2\varepsilon}} d\xi}, \quad (8)$$

where

$$G(\xi) = -\int_0^\xi u_0(\eta) d\eta + \frac{(x - \xi)^2}{2t}.$$

The behavior of the exact solution (8) as $\varepsilon \rightarrow 0$ can be obtained by observing that the dominant contributions

to the integrals in (8) come from the neighborhood of the stationary points of G where

$$\frac{\partial G}{\partial \xi} = -u_0(\xi) - \frac{x - \xi}{t} = 0. \quad (9)$$

If (9) has only one stationary point, by the application of the steepest descent method, the asymptotic solution $u(x, t; \varepsilon)$ as $\varepsilon \rightarrow 0^+$ converges strongly to

$$u(x, t) = u_0(\xi), \quad x = \xi - u_0(\xi)t. \quad (10)$$

The above is exactly the solution of the Cauchy problem for the Hopf equation (2). The stationary point $\xi(x, t)$ of (9) becomes the characteristic variable in (10). For bump-like initial data the solution of the Hopf equation (2) has a point of gradient catastrophe (x_c, t_c) . After the time $t = t_c$ of gradient catastrophe, (10) gives a multivalued solution: the characteristics of the Hopf equation begin to intersect. For a typical initial pulse, there are usually three characteristics that intersect at each point of the multivalued region; that is, (9) has three solutions $\xi_1(x, t)$, $\xi_2(x, t)$, $\xi_3(x, t)$, $\xi_1 > \xi_2 > \xi_3$. The dominant behavior of the solution of the Burgers equation will be given by the following contributions:

$$u \simeq -\frac{\sum_{i=1}^3 \frac{x - \xi_i}{t} |G''(\xi_i)|^{-\frac{1}{2}} e^{-\frac{G(\xi_i)}{2\varepsilon}}}{\sum_{i=1}^3 |G''(\xi_i)|^{-\frac{1}{2}} e^{-\frac{G(\xi_i)}{2\varepsilon}}}. \quad (11)$$

Let us suppose that for $x_c < x < x_s$ and $t > t_c$, the function $G(\xi_1(x, t))$ is less than $G(\xi_2(x, t))$ and $G(\xi_3(x, t))$. Then the above expression for u in the limit $\varepsilon \rightarrow 0$ reads

$$u \simeq -\frac{x - \xi_1}{t}, \quad x_c < x < x_s, \quad (12)$$

while assuming that for $x > x_s$ $G(\xi_2(x, t)) < G(\xi_1(x, t))$, $G(\xi_3(x, t))$, we have

$$u \simeq -\frac{x - \xi_2}{t}. \quad (13)$$

In each case, (10) applies to both ξ_1 and ξ_2 . Therefore, the solution of the Burgers equation converges as $\varepsilon \rightarrow 0^+$ to the solution of the Hopf equation (2) almost everywhere except at the points (x, t) where $G(\xi_i(x, t)) = G(\xi_j(x, t))$, $i \neq j$, $i, j = 1, 2, 3$. For example, in the case treated above, the change over from ξ_1 to ξ_2 occurs when $x = x_s$ where $G(\xi_1) = G(\xi_2)$. Near $x = x_s$ the solution of the Burgers equation as $\varepsilon \rightarrow 0^+$ has a transition from (12) to (13) which is called a shock wave. In other words, the solution of the Burgers equation in the zero viscosity limit is given by two different branches of the solution of the Hopf equation joined by a jump at the point x_s . The condition $G(\xi_1) = G(\xi_2)$ reads

$$\begin{aligned} & -\int_0^{\xi_1} u_0(\eta) d\eta + \frac{(x - \xi_1)^2}{2t} \\ & = -\int_0^{\xi_2} u_0(\eta) d\eta + \frac{(x - \xi_2)^2}{2t}. \end{aligned}$$

Because of (10), the above relation is equivalent to

$$\frac{1}{2}(u_0(\xi_1) + u_0(\xi_2)) = \frac{1}{\xi_1 - \xi_2} \int_{\xi_2}^{\xi_1} u_0(\eta) d\eta, \quad (14)$$

which describes the shock wave. Since the shock occurs at $x = x_s(t)$, $t > t_c$, we also have

$$x_s(t) = \xi_1 - u_0(\xi_1)t, \quad x_s(t) = \xi_2 - u_0(\xi_2)t.$$

The above three equations determine the functions $x_s(t)$, $\xi_1(t)$, and $\xi_2(t)$. The values of $u(x, t)$ on the two sides of the shock are $u^-(x, t) = u_0(\xi_1(x, t))$ and $u^+(x, t) = u_0(\xi_2(x, t))$. The shock speed can be derived by taking the time derivative of the above two equations and reads

$$\frac{dx_s(t)}{dt} = -\frac{1}{2}(u_0(\xi_1) + u_0(\xi_2)).$$

Comparison of the above relation with (14) shows that the modulus of the shock speed is equal to the average value of the characteristics velocity $u_0(\eta)$ over the interval $[\xi_1, \xi_2]$.

While the zero-dispersion limits have been studied only for integrable equations such as the KdV or the nonlinear Schrödinger equation, the zero-viscosity limits have been studied for the parabolic equation of the form

$$u_t + [f(u)]_x = \varepsilon u_{xx}, \quad u \in R^n, \quad (t, x) \in R \times R^m.$$

The scalar case in several spatial dimensions was investigated by Kruzhkov (1970). The two-component case in one spatial dimension has been studied by DiPerna (1983), while the n -component case in one spatial dimension has been investigated by Bressan (2002).

Synoptic view of surface winds over the Atlantic Ocean on September 13, 1999. The background colors indicate wind speeds and the white arrows show the direction of the wind. The high winds of Hurricane Floyd can be seen east of the Bahamas. The images are obtained from the NASA/NOAA sponsored data system Seaflux, at JPL through the courtesy of W. Timothy Liu and Wenqing Tang. (See **Atmospheric and ocean sciences; Hurricanes and tornadoes; Vortex dynamics in fluids.**)

The planet Jupiter showing the Great Red spot, photographed by the NASA Cassini satellite on December 29, 2000. Courtesy NASA/JPL/ Space Science Institute. (See **Fluid dynamics; Jupiter's Great Red spot; Vortex dynamics of fluids.**)

Overhead view of Hurricane Andrew on 25 August 1992 at 20:20 Universal Time (UT). Different wave-lengths are assigned to the red, green, and blue channels to make the hurricane appear red. Courtesy of National Oceanic and Atmospheric Administration. (See **Atmospheric and ocean sciences; Hurricanes and tornadoes; Vortex dynamics of fluids.**)

Aircraft wake vortex visualized by colored smoke. NASA's Wake Vortex Study at Wallops Island, 1990. Courtesy of NASA Langley Research Center. (See **Fluid dynamics; Vortex dynamics in fluids.**)

An atmospheric flow pattern known as the von Karman vortex street—a linear chain of spiral eddies. The vortex pattern is made visible by the marine stratocumulus clouds around Guadalupe Island, which is about 22 miles long and lies about 250 miles southwest of San Diego. Multi-angle Imaging Spectroradiometer (MISR) images from June 11, 2000; NASA/ GSFC/JPL, MISR Team. (See **Fluid dynamics; Turbulence; Vortex dynamics of fluids.**)

Close-up view of coherent vortex structure from direct numerical simulation of homogeneous isotropic turbulence: (a) streamlines, and (b) vortex lines—color-coded according to intensity—forming a tangle of space curves in a reference box (tropicity domain). Courtesy of Z.-S. She, E. Jackson and S.A. Orszag, Princeton University, Princeton, NJ, USA. (See **Structural complexity; Turbulence.**)

The Sun, imaged in three color-coded wavelengths (171, 195 and 284 angstrom), showing solar flares (sun spots) comprising coronal mass ejections which launch solar winds. Courtesy of SOHO/Extreme Ultraviolet Imaging Telescope (EIT) consortium. SOHO is a project of international cooperation between ESA and NASA. (See **Alfvén waves**; **Nonlinear plasma waves**.)

Pumice and ash erupting from Mount St. Helens on May 18, 1980 is a powerful example of turbulent dispersion of small particles. The plume eventually reached 12 to 15 miles (20–25 km) above sea level. Photograph by Donald A. Swanson, USGS/CVO. (See **Evaporation waves**; **Plume dynamics**.)

Lifetimes of perturbations in a planar shear flow for different values of initial energy (E) and Reynolds number (Re). In the transition region the lifetimes show a sensitive dependence on initial conditions and huge fluctuations. Similar behavior has been observed in plane Couette flow and in pipe flow. (See **Fluid dynamics**; **Shear flow**.)

Red and green colors predominate in this view of the Aurora Australis photographed from the Space Shuttle in May 1991. Long a source of myth, auroras are known from late nineteenth-century studies by Kristian Birkeland to be driven by solar wind and stabilized by Earth's magnetosphere. Photograph by the STS-39 Crew, courtesy of Earth Sciences and Image Analysis Laboratory, NASA Johnson Space Center. (See **Alfvén waves**; **Nonlinear plasma waves**.)

Turbulent clouds of hydrogen gas mix with small amounts of oxygen, sulfur, and other elements in this Hubble Space Telescope image of a region of M17, a nebula about 5,500 light-years away that is giving birth to new stars. Ultraviolet energy from hot, young stars in the nebula causes the gas to glow, and the intense heat and pressure cause turbulence. The different colors represent different gases. Courtesy of NASA/ESA/J. Hester (ASU). (See **Galaxies**.)

A slice from a three-dimensional numerical simulation of turbulent flow around a square cylinder (visible at the bottom of the image). The data is visualized using the spot noise technique to show flow structure, color shows the pressure. Simulation by R. Verstappen and A. Veldman of the University of Groningen in the Netherlands, and visualization by W. de Leeuw and R. van Liere of the Center of Mathematics and Computer Science in Amsterdam. (See **Fluid dynamics**; **Turbulence**.)

Snapshot of the results of a simulation for a toroidal magnetic confinement system called a tokamak. Contours of $E \times B$ reveal ballooning turbulence. Turbulence is on a relatively short scale perpendicular to the magnetic field and very extended along the magnetic field lines. The eddies tend to point preferentially in the direction of positive (bad) magnetic curvature. Photograph courtesy of Gary Kerbel, National Energy Research Supercomputer Center. (See **Nonlinear plasma waves**.)

(See **Nonlinear plasma waves**.)

Electrically driven convection in a smectic (the most ordered phase) liquid crystal film. (a) A nonuniformly thick film is freely suspended between two wires about 1mm apart. The film itself is less than 1 micron thick, and shows bright interference colors under reflected white light, like a soap bubble. The film convects when a DC voltage of a few volts is applied to the wires. The vortex flow is visualized as it advects the thickness variations. The driving mechanism involves the field coupling to the surface charge which develops on the film's two free surfaces. This system forms a simple one-dimensional nonlinear pattern which has been quantitatively studied in films with perfectly uniform thickness, for which no color variation is visible. (b) As in the previous figure, now with annular electrodes and a radial driving force. One can also rotate the inner electrode and thus study convection superposed on a two-dimensional circular Couette flow. Images courtesy of Stephen W. Morris, University of Toronto. (See **Liquid crystals**; **Spatiotemporal chaos**; **Thermal convection**.)

Closed Rayleigh-Bénard convection cells in clouds over the South Atlantic Ocean. NASA/GSFC. (See **Atmospheric and ocean sciences**; **Fluid dynamics**; **Pattern formation**; **Thermal convection**.)

Evolution of oscillatory convection in a binary fluid layer heated from below. The concentration distribution in a vertical cross section of the fluid layer is displayed by color coded plots with blue and red denoting high and low concentration, respectively. Wave profiles at midheight are shown for the fields of vertical velocity (thin lines), temperature (lines with triangles), and concentration (lines with squares). Initially a standing wave grows ($t = 6.3$). It breaks at $t = 10.3$ and is thereby transformed into a fast traveling wave propagat-

ing to the left which then slows down. For better visibility two wavelengths are shown. (See **Fluid dynamics**; **Rayleigh-Taylor instability**; **Thermo-diffusion effects**.)

Numerical results from a coupled atmosphere-ocean model of the North Atlantic circulation including bottom topography (a) now and (b) the prediction for 100 years from now. Noticeable are the divergence of the Gulf Stream in the North Atlantic, reduction in the production of deep cold water masses near Greenland, and slowing of part of the global conveyor belt. Relevant streamlines of the general circulation are colored according to their temperature (red=warm, blue=cold). Courtesy of the Deutsches Klimarechenzentrum (Michael Böttinger, DKRZ, Hamburg, Germany). (See **Atmospheric and ocean sciences**.)

Spatially confined convection in binary fluid mixtures in the form of a localized traveling wave. (a) Concentration deviation (δC) from global mean (light green/yellow) in a vertical cross section of the layer. (b) Lateral wave profiles at mid-height, $z = 0$, of δC (green), vertical velocity w (blue), and its envelope. (c) Phase velocity v_p (black) and mixing number M (green) measuring rms deviations of concentration. (d) Time averaged deviations from the conductive state at $z = -0.25$ for concentration (green), temperature (red), and their sum ((b)) measuring the convective contribution to the buoyancy. (e) Streamlines of time averaged concentration current J (green) and velocity field u (blue). Thick blue and green arrows indicate u and transport of positive δC (alcohol surplus), respectively. Thus, in the lower half of the layer negative δC (water surplus) is transported to the right. (See **Fluid dynamics**; **Thermo-diffusion effects**.)

Snowflakes on a window pane. Ice crystals are now recognized as examples of nonlinear pattern formation. (See **Growth patterns; Pattern formation.**)

Dune fields with a regular pattern, Lençóis Maranhenses National Park, on Brazil's north coast. Image courtesy of Earth Sciences and Image Analysis Laboratory, NASA Johnson Space Center, ISS007-E-15177. (See **Dune Formation; Geomorphology and tectonics; Pattern formation.**)

Self similarity of a fern frond. There is a limit to the range of scales at which the self similarity is maintained, and it occurs at only a few discrete scales. Courtesy of Paul Bourke. (See **Fractals; Turing patterns.**)

Bacterial colonies develop complex spatiotemporal patterns in response to adverse conditions such as nutrient starvation. (a) Branching pattern in a Petri dish of *Paenibacillus dendritiformis*. Growth rate is limited by diffusion of nutrients towards the colony, giving a branching or fractal pattern. (b) Vortex branching exhibited by *Paenibacillus vortex* bacteria. At the dark dot at the tip of each of the branches, millions of bacteria rotate in a highly organized vortex. Chemorepellents push the vortices outwards, allowing the colony to expand. Images courtesy of Eshel Ben Jacob, Tel Aviv University. (See **Cluster coagulation; Growth patterns.**)

Computer simulation of growth in three dimensions by diffusion-limited aggregation. Such growth patterns are natural fractals. Courtesy of Paul Bourke. (See **Cluster coagulation; Fractals; Growth patterns.**)

Approximate self similarity in the Mandelbrot set. The Mandelbrot set is the set of all c for which the iteration $z \rightarrow z^2 + c$, starting from $z=0$, does not diverge to infinity. This set is named after the mathematician Benoit Mandelbrot, who discovered their fractal and self replicating structure. Three successive magnifications are shown, and at each level a structure similar, but not exactly the same, as the entire set is observed. Courtesy of Paul Bourke. (See **Fractals; Multifractal analysis.**)

Drainage networks have scale-invariant (fractal) symmetry. Top: Color image of elevation (white/yellow = high elevation black/red = low elevation) and drainage network (black lines) for a river basin in the Loess Plateau region of the Shanxi Province, P.R.C. River basins in homogeneous material such as loess (a silty soil deposited by wind storms) form particularly symmetric and ordered networks. Bottom: Color image of elevation for a fluvial landscape evolution simulation. Courtesy of Jon Pelletier, University of Arizona. (See **Geomorphology and tectonics.**)

The elephants image is a Julia set with an unusual initialization scheme. The image plane is mapped to the 3rd power of the pixel coordinate. This has the effect of increasing symmetrical order. Maximum iterations/ pixel = 1024, center coordinates = $(+3.4861 \times 10^{-14}, -4.88498 \times 10^{-15})$, magnification = 0.9662319. The Julia set coordinate, $p1 = (0.28767393, 0.01500042)$, $z = \text{pixel}^3$; $z = z^3 + p1$, $(|z| \leq 4)$. Image courtesy of Noel Giffin. (See **Maps in the complex plane.**)

A classic Mandelbrot image created with high iteration limits. Maximum iterations/pixel = 300,000, minimum iterations/pixel = 9587, center coordinates = $(+0.37873904887513700, +0.22838619041160610)$, magnification = 8.279722×10^{10} . High iteration fractals can reveal striking fractal detail as the iteration count and zoom depth increase. A logarithmic coloring algorithm is used to distribute the color palette over the large iterative range. Image courtesy of Noel Giffin. (See **Maps in the complex plane.**)

Spiral wave patterns in a BZ reaction, confined to a thin layer in a petri dish. Early on in the reaction, the fronts of the target pattern are far apart, but as the reaction proceeds they become closer and additional wave sources appear, producing a complicated pattern. Courtesy of S.K. Scott, University of Leeds. (See **Belousov-Zhabotinsky reaction; Chaotic dynamics; Reaction-diffusion systems.**)

Simulation of spiral defect chaos in Rayleigh-Bénard convection. Color corresponds to temperature, increasing from violet to red. Local spirals are erratic in time—changing position and size. Courtesy of James D. Gunton, Lehigh University. (See **Spatiotemporal chaos; Spiral waves; Thermal convection.**)

Turing structures of different symmetries obtained with the chlorite-iodide-malonic acid reaction. Dark and light regions respectively correspond to high and low iodide concentration. The wavelength (a function of kinetic parameters and diffusion coefficients) is of the order of 0.2 mm. All patterns in (a)–(d) are at the same scale: view size 1.7 mm $\times$ 1.7 mm. Courtesy P. De Kepper, CRPP. (See **Turing patterns.**)

A montage of planetary images taken by spacecraft managed by the Jet Propulsion Laboratory in Pasadena, CA. (Pluto is not shown.) The emergence of our planets from a cloud of gas and dust about 4.5 billion years ago was a highly nonlinear event. In his work to solve the three-body problem of planetary motion, Henri Poincaré first formulated the basic concepts of chaotic dynamics. Courtesy of NASA. (See **N-body problem; Solar system.**)

Re-creation of the famous 1834 first sighting of a soliton or solitary wave on the Union Canal near Edinburgh, 12 July 1995. Copyright Heriot-Watt University, used with permission. (See **Solitons, a brief history.**)

The baryon density isosurface of a 17-Skyrmion (topological charge of 17). The color represents the value of the third component of the pion field. (See **Skyrmions.**)

Visualization of chaos generated by the one-dimensional map $x_{n+1} = 2x_n$ (left panel), and a similar image for a truly random process (right panel). The “random walk trajectories” are plotted in the complex plane using steps of the same length but the direction is defined by x_n , i.e., $Z_{n+1} = Z_n + \exp(2\pi i x_n)$. Initial conditions for red and blue chaotic trajectories in the equation for the one-dimensional map differ only by a distance 2×10^{-9} . (See **Chaotic dynamics**.)

Infrared image of a spin mode in the free-radical-frontal polymerization of an acrylate in a 1.5 cm diameter tube. Image courtesy of J. Pojman. (See **Polymerization**.)

RNA polymerase active site. The DNA template and growing RNA strands are shown in purple with gold phosphorous atoms; the protein backbone is shown in blue; protein atoms are colored red for oxygen, blue-green for carbon, and blue for nitrogen. The green sphere is a magnesium ion, which coordinates both the protein and the nucleotide tri-phosphate which is being added to the growing DNA strand. Atomic coordinates are available using the protein data bank accession code 116H. Produced with VMD. (See **Protein structure**.)

Numerical simulations of a dripping water faucet. The dripping faucet is a familiar example of chaotic dynamics. (See **Chaotic dynamics**; **Dripping faucet**.)

Dripping patterns of water drops falling from a nozzle (7 mm inner diameter and 10 mm outer diameter) into a transparent cylindrical container of salad oil, which sensitively depends on the flow rate. The salad oil was used only to decrease the acceleration of the drops to obtain successive pictures. Examples of period-one (left), period-two (middle) and chaos (right) are presented. (See **Dripping faucet**.)

RNA polymerase catalytic subunit with DNA bound at the catalytic site. The nucleic acids are shown in purple, as in active site figure. The protein backbone is shown in red, with amino acid side chains colored according to charge and polarity; negatively charged amino acids are red, positively charged amino acids are blue, non-polar amino acids are white, and polar but uncharged amino acids are green. The patterns of charge, hydrogen bonds, and shape are recognized by other proteins in order to regulate activity of this protein. (See **Protein dynamics**.)

RNA polymerase transcription initiation complex, shown with several of the additional proteins necessary for it to function. Different colors represent different proteins interacting with the catalytic subunit. The interactions are quite specific. (See **Protein dynamics**.)

A periodically forced damped pendulum has complex behavior. These computer-generated images show initial positions that map to one of several different behaviors (one color for each). For example, orbits starting at points in the blue region would yield a different type of asymptotic motion than orbits starting in the red region. The brighter the shade of color, the longer it takes to settle into the corresponding motion. The different regions are separated by fractal basin boundaries. The pictures are made at increasing magnification levels. Courtesy, University of Maryland Chaos Group. (See **Attractors; Damped-driven anharmonic oscillator; Pendulum.**)

Three chaotic attractors arising from numerical solutions of a spatially homogeneous model of the mammalian electroencephalogram. Each attractor was constructed by delay-embedding a single state variable corresponding to the electroencephalographic observable. Attractors were rendered from two different viewpoints (left and right images), from 100,000 point time series of 10 seconds total duration and colored by velocity. All attractors have a dominant frequency of oscillation in the electroencephalographic alpha band (8–13 Hz). The top attractor has a Lyapunov dimension of 2.086 ± 0.003 , representing an upper bound for the correlation (D_2) dimension. Graphics by Paul Bourke, Centre for Astronomy and Supercomputing, Swinburne University of Technology, Melbourne, Australia. (See **Electroencephalogram at mesoscopic scales.**)

Chaos in a spatially homogeneous version of Liley et al.'s theory of the mammalian electroencephalogram. The two independent axes represent neuronal population input parameters, whereas the dependent variable (indicated by height and color) represents the largest Lyapunov exponent (LLE) of the system dynamics. Each point in this plane can be thought of as indexing a particular attractor (see previous figure). Green represents limit cycle ($LLE = 0$) activity, whereas points above and below this plane correspond to chaos ($LLE > 0$) and point attractor dynamics ($LLE < 0$) respectively. (See **Electroencephalogram at mesoscopic scales.**)

Standard Map (a): Dynamics of the standard map for $k = 0.6$; (b). Dynamics of the standard map for $k = 2.0$; (c). Dynamics of the standard map for $k = k_c(\gamma) = 0.971635406$. (See **Standard map.**)

Smale's solenoid, an Axiom-A attractor. At each iteration, the fat torus is mapped into a long, thin torus which is then put back into the original torus, winding around twice. Reprinted

from *A First Course in Dynamics*, Hasselblatt & Katok with the permission of Cambridge University Press. (See **Anosov and Axiom A systems.**)

Second harmonic generation in lithium niobate: (a) Experimental setup; (b) Closeup view of the observation screen showing the fundamental and second-harmonic light; (c) Side view showing the partial conversion of the red 800-nm incident

beam into the blue 400-nm beam; the separation of the colors by the prism is relatively small in the plane of this photograph. (See **Frequency doubling.**)
